In recent years, **specific genetic abnormalities** have been found in the majority of RCCs. Based on histologic, cytogenetic, and molecular studies, RCCs are now considered to be a **histogenetically heterogeneous group of distinguishable tumors with significantly different prognoses** (Thoenes, 1986; Kovacs, 1991; Van den Berg et al, 1993; Weiss et al, 1995). Most of these tumors are malignant, but a small minority are now recognized as benign. As a result, a **new classification** of renal neoplasms (shown in Tables 40-1 and 40-2) has gained acceptance (Kovacs et al, 1997; Storkel et al, 1997). This classification, in addition to documenting a close relationship between the morphologic and genetic features of renal tumors, also defines distinct clinical entities (Motzer et al, 1996). Within the malignant categories, different morphologic variants have significant differences in 5-year survival rates (Reuter and Gaudin, 1999).

It is now recommended that the old term *clear cell carcinoma* be replaced by **conventional carcinoma**, with *clear cell* added in parentheses as an afterthought. Although previously used terms such as *granular cell* and *sarcomatoid type of RCC* (Murphy et al, 1994) are no longer recommended, to us they define specific morphologic subgroups and will be used in this text. The rationale behind this change is based on the common origin of these morphologic variants from proximal convoluted tubules, and the shared loss of the short arm of chromosome 3 (3p-) (Table 40-2). Whether the new classification is clinically superior to the old one remains to be seen.

Staging and Grading

In 1969, Robson and associates published a **staging system** for RCC that has been widely accepted and correlates well with survival. The system has been repeatedly modified. In the latest modification, Fleming et al (2002) proposed that **stage 1 and 2** cancers be defined as organ-confined with tumor sizes of <7 cm and >7 cm, respectively. **Stage 3** tumors extend to perinephric tissue (**3a**), renal vein or vena cava (**3b**), or vena cava above the diaphragm (**3c**).

Stage 4

P.1466

tumors invade beyond Gerota's fascia, or are metastatic to distant organs. Metastases to regional lymph nodes upstages stage 1 and 2 tumors to stage 3 tumors.

TABLE 40-2 RENAL CELL NEOPLASMS: PRESUMED CELL OF ORIGIN AND CYTOGENETIC ABNORMALITIES*

Cell of Origin	Tumor Type	Primary Cytogenetic Abnormality
Proximal convoluted tubule	Conventional RCC (subtypes included)	-3p (up to 96%), also +5q, -14q
Distal convoluted tubule	Papillary RCC (PRCC) and metanephric "adenoma"	+7, +17, also +3q, -Y
Intercalated cells (cortex)	Oncocytoma	-Y, -1, -14, t(11)
	Chromophobe RCC (ChRCC)	-Y, -1, -2, -6, -10, -13, -17, -21
Collecting duct cells (medulla)	Collecting duct carcinoma (CDC)	-1, -6, -14, -15, -22, -8p, -13q
	Medullary carcinoma	Unknown (sickle cell trait)

RCC, renal cell carcinoma; p, short arm of the chromosome; q, long arm of the chromosome; t, translocation; -, loss; +, gain.

* modified from Reuter and Gaudin, 1999.

The prognosis of renal cancer depends on the stage and, to a lesser degree, the **grade of the tumor** (Skinner et al, 1971; Bennington and Beckwith, 1975; Colvin and Dickersin, 1978). Several grading systems have been proposed over the years, but the scheme put forth by Fuhrman et al (1982) based on nuclear size, nuclear membrane irregularity, and nucleolar prominence is the most practical and widely accepted. It is summarized in Table 40-3.

The grading system can be adopted, and the tumor grade appended to reports of FNA biopsy of conventional RCC, provided it is understood that variations in grade exist in a given tumor and even within a given field. Therefore, sampling can be a problem in limited cytologic material, and undergrading is more likely to occur than overgrading. Except for conventional RCC, the clinical utility of grading has not been demonstrated.

Attempts have been made to replace nuclear grading with measurements of DNA ploidy, although the value of DNA measurements in such tumors is uncertain (review in Koss et al, 1989). Cajulis et al (1993) reported a reasonable, but not perfect, correlation between nuclear grade and DNA ploidy patterns established by flow cytometry. In their study, all of the aneuploid tumors had a high nuclear grade, but not all of the diploid tumors had a low nuclear grade.

TABLE 40-3 FUHRMAN'S GRADING OF CONVENTIONAL RENAL CELL CARCINOMA

Grade	Nuclear size	Nuclear shape	Nucleolus
1	10	Round, uniform	Inconspicuous
2	15 µm	Irregular	Visible
3	20 µm	Obviously irregular	Large
4	>20 µm	Bizarre, spindle or giant	Macronucleolus

Conventional RCC

Classification and Clinical Data

Based on the new classification, renal carcinomas (previously classified as **clear cell**, **granular cell**, **papillary**, **tubulopapillary**, or **sarcomatoid** types) are included in the category of **conventional RCC**, and account for approximately 60% of all renal tumors.

Clinically, RCC is considered the great imitator (Ochsner et al, 1973). The **classic symptoms** at the time of diagnosis are **hematuria, flank pain, and a palpable mass**, each of which occurs in less than 50% of cases (Ritchie et al, 1983). **Nonspecific symptoms** may include **fever, night sweats, weight loss, hypertension**, and, rarely, **erythrocytosis, anemia, and hypercalcemia** (Skinner and deKernion, 1978; Brodsky and Gavnick, 1989). A significant percentage of cases are **asymptomatic incidental findings** diagnosed by abdominal US or CT during workups for other diseases (Konnack and Grossman, 1985; Thompson and Peck, 1988; Porena et al, 1992).

P.1467

Figure 40-6 Conventional renal cell carcinoma (RCC). *A.* Gross picture of a 2-cm conventional RCC in the inferior pole of left kidney. The tumor was asymptomatic, an incidental finding on imaging. Note the golden-yellow cut surface. *B.* Histology: conventional RCC, clear cell type. Note the microtubule or acinar pattern and multiple nuclei in many cells. This is a grade 1 tumor. *C.* RCC with predominantly granular cells. The gross appearance is dark yellow to brick red. This large tumor (16 cm in diameter) presented as a left abdominal mass and flank pain. *D.* Histology of conventional RCC with predominantly granular cells. Note the presence of cytoplasmic vacuoles containing fat and glycogen. The nuclei are larger and some irregularly shaped, with visible nucleoli; therefore, this is a grade 2 tumor. *E.* Conventional RCC with predominantly sarcomatoid growth. The gross appearance is fleshy white. *F.* Histology of spindly (sarcomatoid) RCC.

P.1468

The **behavior** of RCCs is unpredictable. In some patients, the primary tumor is **occult** and the patient is seen because of **metastatic disease**, commonly in the **bone, lung, liver, or subcutaneous tissue**. In other patients, **metastases of RCC may occur many years after nephrectomy**. **Unexpected sites of metastases that can mimic a primary tumor are the thyroid, ovary, salivary gland, and, rarely, pancreas** (see appropriate chapters). Finally,

RCC in metastatic sites may express a morphologic pattern that is very different from the primary tumor, with the spindle-cell pattern being the most common. The recognition of metastatic renal cancer is often a diagnostic challenge.

A diagnostically valuable **immunohistochemical feature** of RCCs is the **simultaneous expression of intermediate filaments for keratin** (mainly types 8 and 18) **and vimentin** (Pitz et al, 1997). Although similar phenomena may occasionally be seen in other cancers, notably **thyroid carcinoma**, this feature is very helpful in determining the renal origin of metastatic foci in various organs (Domagala et al, 1988).

Gross Features

Surgically resected RCCs vary in size, from very small (2-3 cm in diameter) to very large (20 cm or more). The **colors** of the cut surface of the tumors show a reasonable correlation with histologic patterns. Thus, **golden-yellow** tumors (Fig. 40-6A,B) are usually composed of clear cells, **brickred** tumors (Fig. 40-6C,D) are granular or oncocytic, and sarcomatoid tumors are **fleshy-white** (Fig. 40-6E,F). The tumor may invade the calyces and the renal pelvis, in which case the voided **urine cytology may be positive** (see Chap. 23). RCCs have a tendency to **invade the renal veins and thence the vena cava. Hemorrhage, extensive necrosis, and cavity formation** within the tumor occur frequently.

Histology

Most renal carcinomas show a mixture of histologic and cytologic patterns of growth, as summarized in Table 40-4.

Although **any tumor may be composed of more than one cell type**, the **most common renal carcinoma is the clear cell type with a classic growth pattern in solid sheets or cords**. This is particularly true for relatively small tumors. **Gland formation** may occur. A rich network of capillaries and larger blood vessels is present. The **cytoplasm** of tumor cells contains **lipid and glycogen**, and the **nucleus is disproportionately small** (Fig. 40-6B).

In some of these tumors, the dominant type is **a cancer cell with denser, more granular and eosinophilic cytoplasm, and more conspicuous nuclear abnormalities**. These tumors were **formerly classified as the granular cell type of RCC** (Fig. 40-6D). They must be distinguished from chromophobe carcinoma, oncocytoma, and rare cases of CDC that may contain similar cells (see below).

TABLE 40-4 MORPHOLOGIC VARIANTS OF CONVENTIONAL RCC

Histologic Patterns
Acinar or glandular
Trabecular
Solid or alveolar
Pseudopapillary

Cell Types

Clear cell

Granular (oncocytic)

Spindly (sarcomatous)

Pleomorphic

Undifferentiated small cell

Some tumors are composed partly or wholly of **spindly cancer cells** (Fig. 40-6F), mimicking a variety of sarcomas (**sarcomatous type of RCC**). According to a large study by de Peralta-Venturina et al (2001), the **sarcomatous change is most common in the conventional type of RCC, but it may also occur in other types of renal cancer, such as papillary, chromophobe, and collecting duct carcinomas**. Many of the patients in that study had tumors of high stage, and their **prognosis was less favorable than that of tumors without this component**.

Some tumors may be composed partly or wholly of **very poorly differentiated large or small cancer cells**. Such **poorly differentiated tumors are sometimes difficult to classify** (see below).

Cytology

Aspirates of RCC often contain **much blood** and may show considerable **necrosis** with cell debris (the latter is particularly evident in **tumors with cystic degeneration**). Within this background, **abundant tumor cells, often anchored to capillaries**, are usually seen. The **types of tumor cells** observed in conventional RCC in FNA smears are listed in Table 40-4. It must be stressed that **various types of cancer cells are often simultaneously present in the same patient. The cytologic classification of these tumors is usually based on the dominant cell type in smears, but is not always representative of the tumor type on histologic examination** (Renshaw et al, 1997b). As mentioned above, a **simultaneous expression of keratin and vimentin** is very helpful in determining the renal origin of tumors (Domagala et al, 1988).

Aspirates of RCC usually show loosely cohesive **flat groups of cancer cells** with clear cytoplasm with poorly defined cell borders and many single cells. The tumor cells may also be seen anchored along capillaries, resulting in a pseudopapillary appearance (Fig. 40-7A). The **clear cancer cells are large** (much larger than benign tubular cells) and have **abundant clear or faintly blue delicate cytoplasm**

P.1469

that is often filled with numerous **small vacuoles** containing **lipid and glycogen but not mucin** (Fig. 40-7B). The vacuoles are better seen in air-dried smears processed with hematologic stains. Phagocytosed **hemosiderin** may be seen. The **nuclei are relatively small, but still much larger than those of benign tubular cells**. They are only **slightly**

pleomorphic, haphazardly placed, **usually hyperchromatic**, and contain **readily visible nucleoli**.

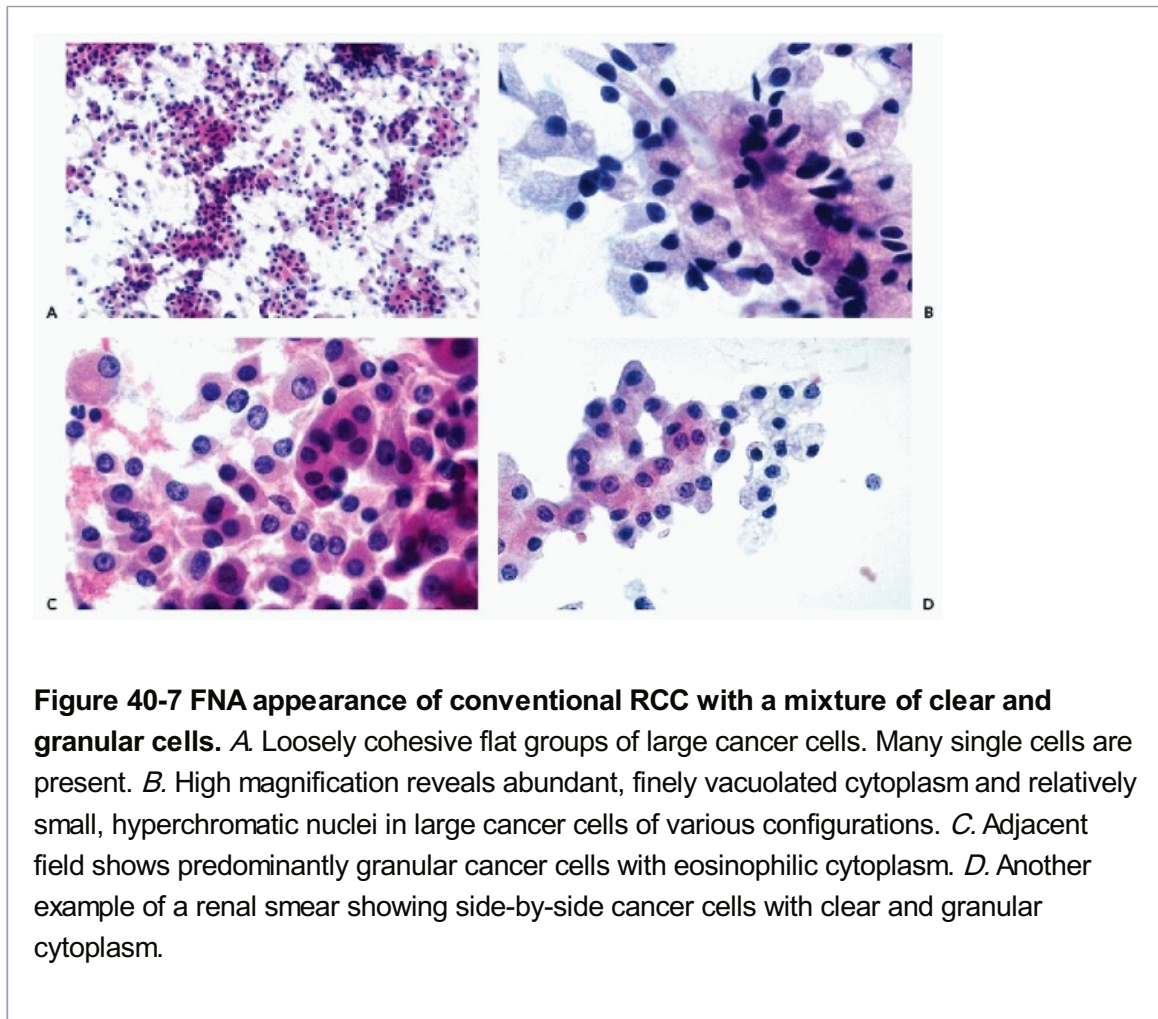

Figure 40-7 FNA appearance of conventional RCC with a mixture of clear and granular cells. *A.* Loosely cohesive flat groups of large cancer cells. Many single cells are present. *B.* High magnification reveals abundant, finely vacuolated cytoplasm and relatively small, hyperchromatic nuclei in large cancer cells of various configurations. *C.* Adjacent field shows predominantly granular cancer cells with eosinophilic cytoplasm. *D.* Another example of a renal smear showing side-by-side cancer cells with clear and granular cytoplasm.

In **low-grade** conventional RCCs, composed predominantly of clear cells, the FNA smears **fixed in 95% ethanol** may show numerous well-preserved **nuclei stripped of cytoplasm (“naked” nuclei)** (Fig. 40-8A,B). This phenomenon is caused by dissolution of the cytoplasmic lipids in alcohol, resulting in cytoplasmic disintegration. “Naked” nuclei may also be observed in metastatic renal cancers. Some of these nuclei contain prominent ruby-red nucleoli, consistent with renal origin.

In **high-grade** conventional RCCs, the malignant nature of the cells is usually quite evident (Fig. 40-8C,D). The cancer cells have large nuclei with prominent, sometimes ruby-red nucleoli, and relatively scanty cytoplasm that is either clear or eosinophilic and granular. It is usually easy to recognize such tumors, and the only point of differential diagnosis may be metastatic carcinomas, which have a different clinical and radiologic presentation.

As illustrated in Figure 40-7, most conventional RCCs show a **mixture of clear cells and granular (oncocytic) cells** in an ample FNA sample. The granular cancer cells have an eosinophilic, granular cytoplasm, are usually **smaller and more uniform than the clear cells**, and have **larger and more atypical nuclei**, and hence a higher N/C ratio. **Cytoplasmic granules**, reflecting **numerous mitochondria**, are well visualized in air-dried smears processed with hematologic stains. In H&E- or Papanicolaoustained smears the granules are **intensely eosinophilic** (Fig. 40-7C,D). In some cases, the granular cells are predominant, but so long as **some clear cells are also present in the smears, the diagnosis of a**

conventional RCC is favored. The eosinophilic cells **may resemble hepatocytes**, which may be obtained in a misdirected FNA smear and mistaken for granular cells of RCC. Normal hepatocytes do not show the nuclear abnormalities seen in granular cancer cells. Lipofuscin and bile, when present in the cytoplasm, provide additional clues to the hepatic derivation of these cells. Weir and Pitman (1997) noted that the characteristic vascular pattern observed in

P.1470

well-differentiated hepatomas was absent in RCC (see Chap. 38).

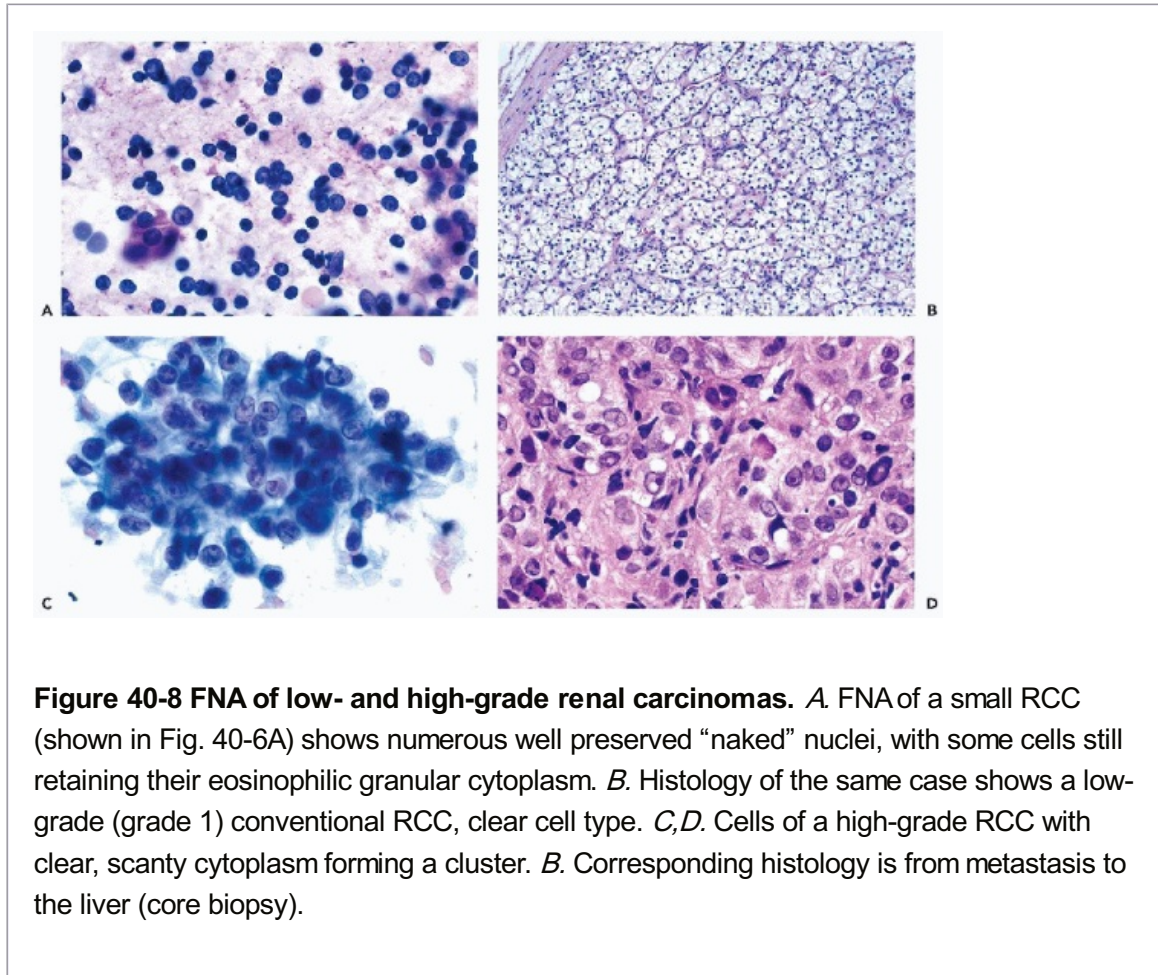

Figure 40-8 FNA of low- and high-grade renal carcinomas. *A.* FNA of a small RCC (shown in Fig. 40-6A) shows numerous well preserved “naked” nuclei, with some cells still retaining their eosinophilic granular cytoplasm. *B.* Histology of the same case shows a low-grade (grade 1) conventional RCC, clear cell type. *C,D.* Cells of a high-grade RCC with clear, scanty cytoplasm forming a cluster. *B.* Corresponding histology is from metastasis to the liver (core biopsy).

Somewhat similar cells may be observed in **two relatively uncommon renal tumors: the oncocyoma and chromophobe renal carcinoma**. Table 40-5 is a summary of salient clinical, cytologic, and ancillary characteristics of **renal tumors with granular cytoplasm**. The very rare collecting duct carcinoma is not included in this table. All of these tumors are discussed below. In addition, Reuter (1999) has reported that **rare cells with granular cytoplasm may occur in angiomyolipoma and metastatic melanoma**.

Among the uncommon cell types of conventional RCCs are undifferentiated cancer cells. This term implies the presence of clearly malignant cells of **variable shapes and sizes with prominent nuclear abnormalities**, but no specific features of RCCs. The cells occur singly or in very loosely structured aggregates, and are sometimes very large and multinucleated. In our experience, the **pleomorphic cells with very large nuclei** are relatively uncommon in renal FNA and always indicate the presence of a high-grade tumor (Fig. 40-9A). **The interpretation of such cells depends on the company they keep.** In the presence of at least some classic cancer cells with clear or granular cytoplasm, the most likely diagnosis is RCC. If the **pleomorphic cells occur alone**, the possibility of a **metastatic carcinoma** from an extrarenal

site must be entertained.

In still other types of tumors, some of the **undifferentiated cancer cells are quite small and occur singly and in small clusters** (Fig. 40-9B). These cells, which have relatively **large hyperchromatic nuclei and scanty, clear cytoplasm**, may occur in conventional RCC and may be accompanied by clear or granular cancer cells. However, similar cells may also be found in **Wilms' tumor, metastatic small cell carcinoma, and a large cell lymphoma**. The interpretation depends entirely on the **smear pattern**, which is quite different in each of these entities (see below).

In some conventional RCCs and in carcinomas composed of spindly cells, the cancer cells tend to be **elongated or spindly** and may be **similar to fibroblasts**. They have **delicate, finely vacuolated, abundant, faintly granular cytoplasm and pleomorphic ovoid to elongated nuclei, usually with prominent nucleoli** (Fig. 40-9C,D). Such cells correspond to areas of the primary tumor that are composed of elongated cells (see Fig. 40-6F), and **may also occur in metastatic foci, mimicking a sarcoma** (Koss et al, 1992).

P.1471

TABLE 40-5 RENAL CELL TUMORS WITH GRANULAR CYTOPLASM

	Oncocytoma	Chromophobe RCC (ChRCC)	RCC With Predominant Granular Cells
Relative incidence	3-7%	6-11%	Not known but common in higher grade lesions (all variants 60%)
Natural history	Essentially benign	Mortality 6%	Mortality 38%
Average tumor size and location	6 cm (central stellate scar in 1/3), often subcapsular	Large (9 cm), cortical	5.5 (recent series)-8 cm (older series); more common in upper pole
Smear pattern	Predominantly isolated cells or small aggregates	More aggregates Some single cells	Loose clusters and single cells, bare nuclei
Cell size and cytoplasmic characteristics	Very large, uniform, low N/C ratio Homogeneous, dense pink granular	Large, pleomorphic with high N/C ratio Dense pink granular cytoplasm with perinuclear pale zones	Medium, uniform to pleomorphic, high N/C ratio. Sometimes vacuolated pink granular cytoplasm

	cytoplasm		
Nuclear features	Uniform, small and round (8-10 μm), Finely granular chromatin Inconspicuous nucleoli No mitoses	Uniform to pleomorphic (10-15 μm) Notched nuclear contour Coarse chromatin Prominent nucleoli	Large (15-20 μm) relatively uniform Fine chromatin, large nucleoli
Ancillary tests	Stain for lipid and glycogen negative EMA positive LMW keratin positive Vimentin negative	Hale's colloidal iron stain positive EMA positive LMW keratin negative Vimentin negative	Stain for lipid and glycogen positive in some cells EMA positive LMW keratin negative Vimentin positive
EMA, epithelial membrane antigen; LMW, low molecular weight; N/C ratio, nucleocytoplasmic ratio.			

Variants of Conventional Renal Cell Carcinoma

Multilocular Cystic Renal Cell Carcinoma

Approximately 3% of conventional RCCs are **multicystic**. Adults on **long-term dialysis constitute a high-risk group** (Truong et al, 1995). The gross appearance of these tumors is that of a **multiloculated cystic mass**, separated from the renal parenchyma by a thick fibrous capsule. The cysts are variable in size and separated from each other by thin fibrous septa. The cyst contents are **serous or bloody**, and are either fluid or clotted. **Golden-yellow rims of tumor** may be visible in some cyst walls, but there are no visible tumor masses (Fig. 40-10A).

In histologic sections the cysts are lined by **one or more layers of neoplastic epithelial cells, occasionally with papillary tufting**. The golden-yellow portions of the cyst wall usually show a **typical RCC** composed of clear cancer cells (Fig. 40-10B). Nonneoplastic stroma shows numerous hemosiderin-laden macrophages.

Cytology

The FNAs yield a **variable amount of fluid**. The smears are sparsely cellular and may show macrophages and leukocytes. The **malignant cells** are often reduced to **bare nuclei with prominent nucleoli** or uniform small cells with clear cytoplasm and bland nuclei (Fig. 40-10C). In sparsely cellular specimens with uniform tumor cells, a diagnosis may be difficult to establish (Kini, 1999). The prognosis is generally excellent (Koga et al, 2000).

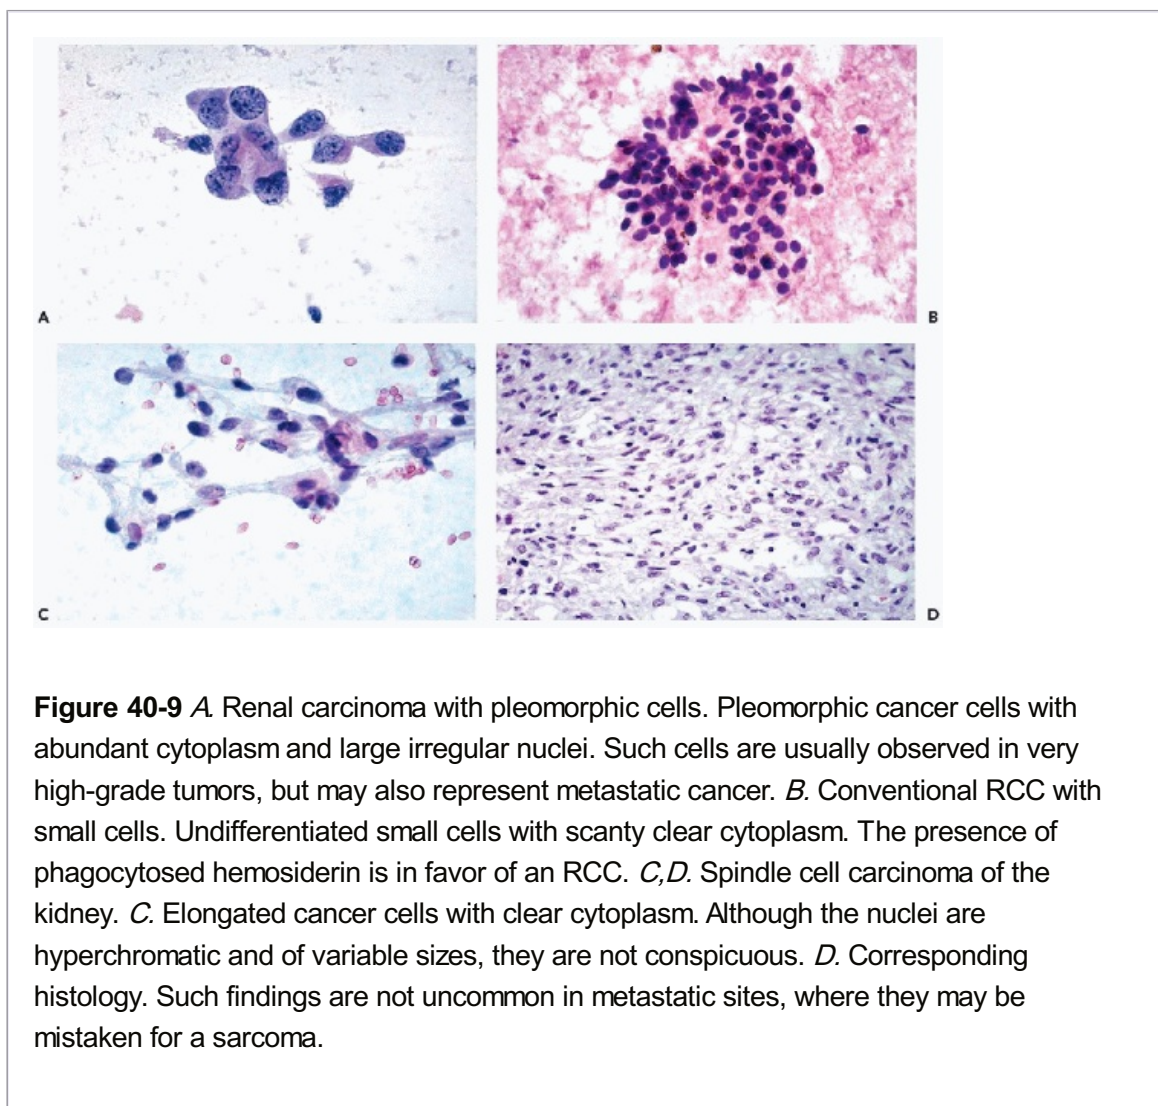

Renal Cortical Adenomas Versus Small Renal Cell Carcinomas

Renal epithelial tumors measuring **less than 3 cm in diameter** are, as a rule, an incidental finding. The tumors are generally benign and for many years have been designated as **adenomas**. However, as early as 1938, Bell (1938) observed that renal tumors measuring less than 3 cm in diameter are **sometimes capable of forming metastases**. The present consensus among urologists and pathologists is **that these tumors represent small RCCs**. The small tumors are either composed of clear cells or they show packed papillary structures lined by cuboidal cells. There are no light-microscopic, immunohistochemical, or electron-microscopic features to distinguish them from conventional RCC of the clear cell type.

Cytology

Because of their small size, these tumors are rarely aspirated. The cytologic presentation is identical to that of a low-grade **conventional (clear cell variant)** of RCC, as described above.

P.1472

Rare Variants

Unger et al (1993) described a variant of RCC with **eosinophilic cytoplasmic globules or inclusions**, which stained magenta in Diff-Quik-stained FNA, in otherwise classic clear cancer cells. The inclusions were thought to represent a form of glycogen. Hirokawa et al (1998) described a conventional RCC with **melanin-like pigment** in the cytoplasm of cancer cells.

Papillary Renal Cell Carcinoma (PRCC or Chromophil Carcinoma)

Papillary RCC (PRCC) represents 7% to 14% of primary epithelial renal tumors. The mean age at the time of diagnosis (61.8 years) is similar to that for conventional RCC. The ratio of males to females is **1.8 to 1**. The tumors are frequently **multifocal** and occasionally **bilateral** (Amin et al, 1997). The tumors, which are of variable sizes at the time of diagnosis, are often **small and located in the poles of the kidneys**, which permits surgical treatment by **partial nephrectomy** (Lager et al, 1995; Renshaw and Corless, 1995). This has been our experience also. These tumors are usually **hypovascular** on angiography, but often show intramural hemorrhage (Fig. 40-11A). **Genetic data** document that PRCC is a **distinct entity** separate from the conventional RCC (see Table 40-2).

It has been known for many years that **papillary carcinoma** of the kidney carries a **much better prognosis** than conventional renal carcinoma (Koss et al, 1992). In a large study, Amin et al (1997) reported an overall 5-year survival rate for PRCC of about 90%, which is much higher than that of conventional RCC (estimated at about 50%). The 5-year survival of patients with stage 1 papillary carcinoma is close to 100% (Robson et al, 1969).

Histology

The hallmark of this tumor is the formation of **papillae** with wide **cores that are filled with large foamy macrophages** (Fig. 40-11B). Delahunt and Eble (1997) observed **two types of epithelial cells** surfacing the papillae. In about two thirds of the cases, the surface of the papillae was formed by **small epithelial cells with pale cytoplasm and oval nuclei**. In the remaining cases, the papillae were surfaced by **large eosinophilic or basophilic (chromophil) epithelial cancer cells with large nuclei**, and hence a high N/C ratio. **The nuclear texture is generally finely granular, and enlarged**

P.1473

nucleoli of moderate sizes are often present. The neoplastic cells often contain large amounts of ingested **hemosiderin** (Fig. 40-10). **Psammoma bodies** are not uncommon, particularly in tumors with large cells. **Solid variants** of PRCC have been described based on **cytogenetic findings** (Renshaw et al, 1997).

Figure 40-10 Multilocular cystic RCC. A. Gross appearance of a multilocular cystic RCC. B. Histologic sections of light-yellow areas show a grade 1 conventional RCC with cystic changes. FNA of multilocular RCC may be unrewarding (see text). C. Sparse tumor cells with clear and vacuolated cytoplasm in a background of macrophages and leukocytes.

Cytology

The cytologic presentation of papillary carcinoma in FNA is quite characteristic and corresponds to the two subtypes described by Delahunt and Eble (1997). In both subtypes, the smears contain a **large number of foamy macrophages with finely vacuolated cytoplasm and small nuclei** derived from the disrupted cores of the papillary fronds. The macrophages form a unique **background** wherein **cancer cells**, occurring singly or in small **papillary clusters**, can be observed (Fig. 40-11C). Two types of cancer cells may be observed. In most cases, the cells are **small and cuboidal**, and are provided with a delicate cytoplasm and relatively small nuclei with prominent nucleoli (Fig. 40-11C). In other cases, the **cancer cells** are larger and approximately **spherical, with eosinophilic cytoplasm; crisp cytoplasmic borders; large, somewhat hyperchromatic, roughly spherical nuclei; and clearly visible nucleoli** of various sizes often arranged in **papillary fronds** (Fig. 40-11D). Cancer cells containing **brown hemosiderin crystals** are common (Fig. 40-11D) and, along with macrophages, constitute a valuable clue to the diagnosis of PRCC. **Psammoma bodies** occur from time to time but are not a constant finding (Dekmezian et al, 1991).

The primary **differential diagnosis** is with **conventional RCC that may sometimes exhibit a pseudopapillary growth pattern**. The homogenous rather than vacuolated cytoplasm of the tumor cells, and the presence of large macrophages, hemosiderin, and occasional psammoma bodies are unique to papillary tumors and allow for an easy distinction to be made in most cases.

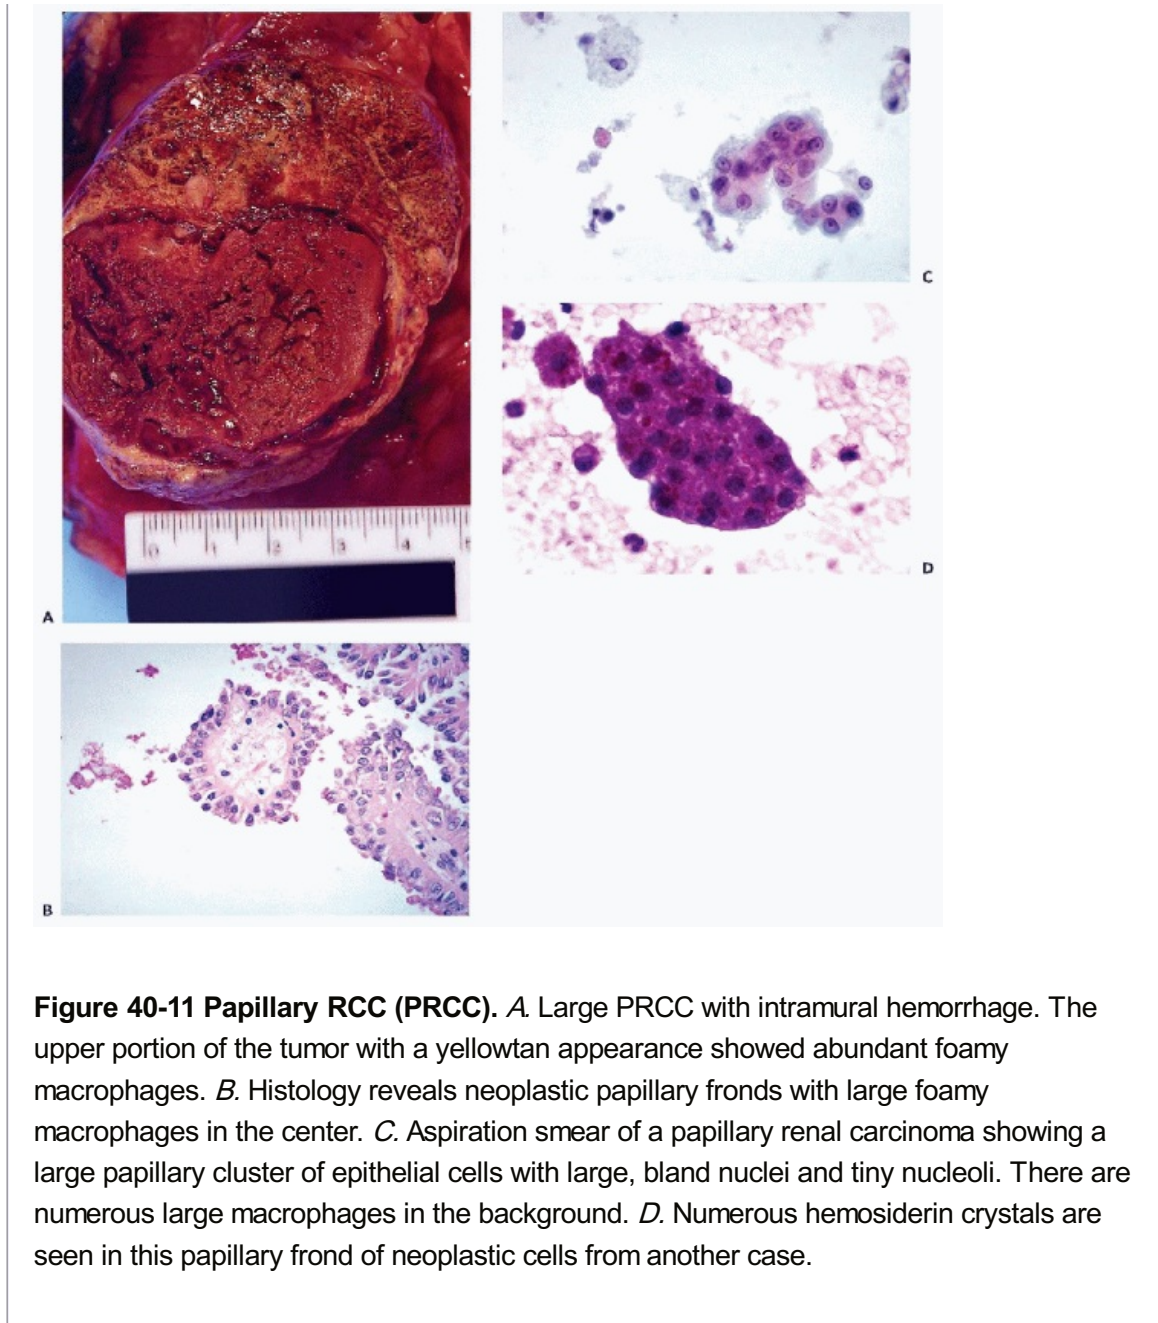

Chromophobe Renal Cell Carcinoma

Thoenes et al (1985, 1988) recognized this relatively uncommon variant of renal epithelial tumors and illustrated its morphologic, histochemical, and ultrastructural features (see Table 40-5). The tumor has a **unique genetic make-up** (see Table 40-2). The age and sex distributions are virtually identical to those seen in conventional RCCs. Most patients with this tumor (60%) are asymptomatic, approximately 30% have a palpable mass, and a minority have hematuria. Stage for stage, ChRCCs carry a significantly **better prognosis** than conventional RCCs.

Grossly, these are large tumors (9 cm in diameter, on average), usually located in the renal cortex. The cut surface is lobulated and gray-brown. **Microscopically**, the tumor is usually composed of **large tumor cells with relatively small nuclei** (10-15 μ m in diameter), forming **solid nests** separated by delicate fibroconnective tissue septa (Fig. 40-12A). The cell membrane is well defined, and the **cytoplasm**

P.1474

in most cases is very pale and transparent (typical chromophobe tumors) or, in some cases, eosinophilic and granular (Fig. 40-12D).

Ultrastructurally, the tumor cells are **rich in cytoplasmic vesicles** that contain acidic mucins, which accounts for the **positive stain of the cytoplasm with Hale's colloidal iron reaction**. In tumor cells with granular cytoplasm, the **density of mitochondria** is increased (Thoenes et al, 1988). ChRCCs with **eosinophilic (acidophilic), granular cytoplasm** may be **confused with oncocytoma** (see below) and, to a lesser extent, with granular cell variants of conventional RCC. In contrast to the common RCCs, however, ChRCCs do not react with vimentin (Thoenes et al, 1988).

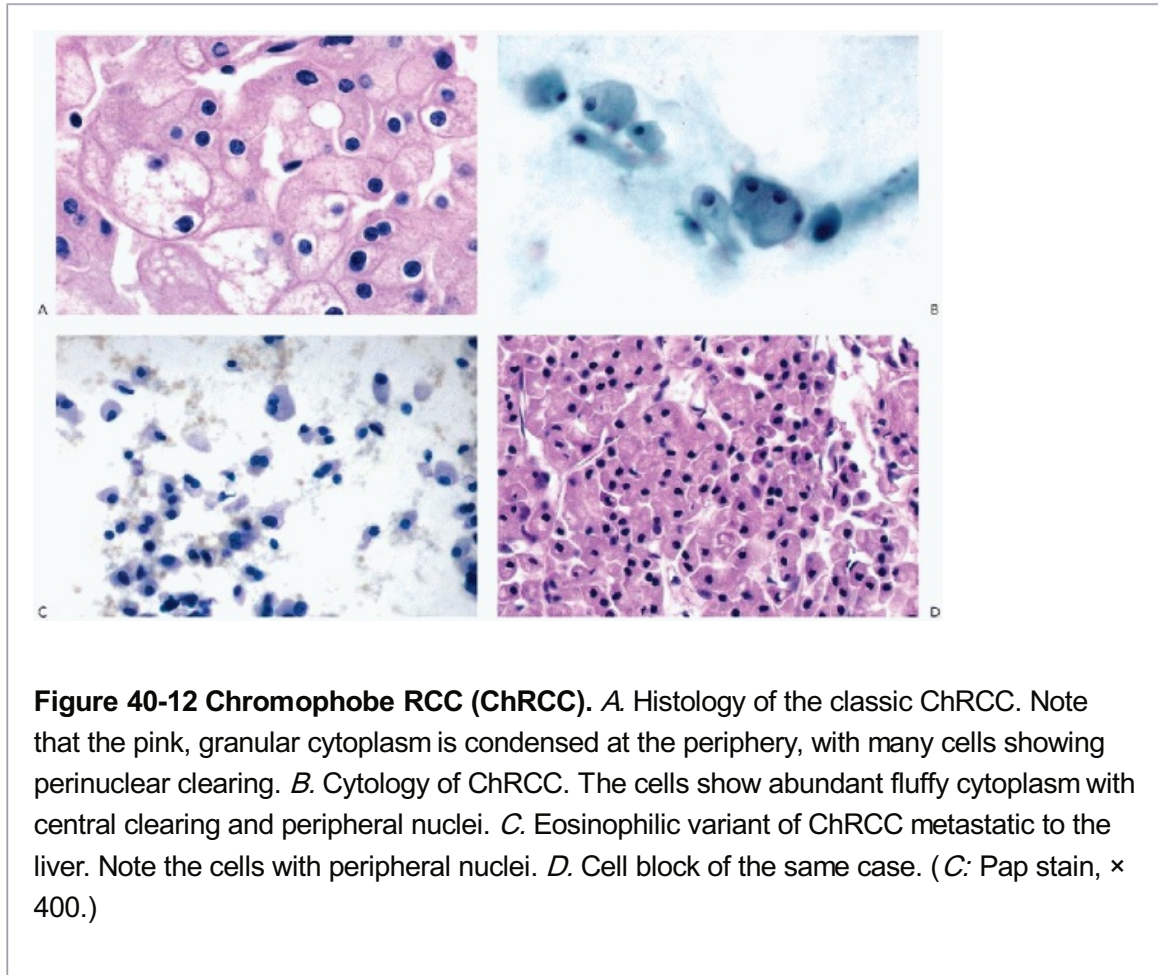

Cytology

These **large tumor cells of variable configuration** have abundant **cytoplasm that is clear or granular in the center of the cell, and condensed at the periphery** (Fig. 40-12B). **Recognizing this cytoplasmic feature is the key to the diagnosis.** The **perinuclear pale zone is somewhat reminiscent of koilocytes**, which are observed in squamous cells in cervical smears from patients infected with human papillomavirus (see Chap. 11). The eosinophilic or granular variant resembles oncocytes or hepatocytes. The **nuclei** are often

peripheral in location, have irregular outlines, and vary somewhat in size but seldom exceed 15 μm in diameter (Fig. 40-12B,C). **Binucleation is common**. Although the **nucleoli** are visible in many cells, they are not conspicuous.

P.1475

Characteristically, the cells stain strongly with **Hale's colloidal iron**, express epithelial membrane antigen (EMA), and are **vimentin-negative** (see Table 40-5).

Oncocytomas

Although renal oncocytomas are **essentially benign**, they are sufficiently similar to renal carcinomas to be described here rather than with benign lesions. This tumor was first described by Zippel (1942) and was largely ignored until the publication of 13 cases by Klein and Valensi (1976). Additional cases were described by Lieber et al (1981). It is estimated that oncocytomas comprise 3% to 7% of all primary renal neoplasms (Reuter and Gaudin, 1999). The majority of the patients are asymptomatic, and the tumor is discovered during workups for other, unrelated conditions. Most series show a wide age distribution, with peak incidence in the seventh decade of life. Men are affected nearly twice as often as women (Amin et al, 1997; Perez-Ordóñez et al, 1997).

On **angiography**, oncocytomas show an **avascular or hypovascular core**, presumably secondary to the central stellate scars that are observed in about one third of the cases. The average tumor size is 6 cm. The cut surface reveals an **encapsulated, uniform, mahogany-brown tumor**. Necrosis and hemorrhage are absent (Fig. 40-13A).

The most common genetic abnormality is **loss of chromosome 1 and Y**, which is also seen in

ChRCC (see Table 40-2). Both tumors are thought to arise from **intercalated cells of the renal cortex**, and may show striking gross and microscopic similarities (see Table 40-5).

As with oncocytic tumors of other organs, such as the salivary glands, thyroid, or parathyroid, renal oncocytomas are composed of **large cells with granular, eosinophilic cytoplasm devoid of vacuoles and supported by delicate fibroconnective tissue septa. The nuclei are small, round, and uniform** (Fig. 40-13B). Of all the renal tumors with eosinophilic cytoplasm (see Table 40-5), **oncocytomas have the smallest nuclei**, measuring 8-10 μm in diameter. Mitotic figures and papillary features are absent. **Microcysts** filled with blood may be present. **Ultrastructurally**, the cytoplasm of tumor cells is packed with **mitochondria** to the virtual exclusion of any organelles other than a few lysosomes. Thus, electron microscopy remains the gold standard for confirming this diagnosis. Stains for lipid and glycogen are negative.

If strict diagnostic criteria are followed and the diagnosis of oncocytoma is limited to tumors composed exclusively

P.1476

of well-differentiated oncocytes with small nuclei, the prognosis is excellent and the tumor is considered to be **benign**. However, there have been reports that at least some tumors may invade the parenchyma of the kidney and may recur (Rodriguez et al, 1980; Lieber et al, 1981). For **tumors diagnosed as oncocytomas that produce metastases, the possibility of misclassification must be considered**. As an example, we recently reviewed a case that was initially classified as oncocytoma and was resected in 1985. Two years later, a mass in the liver was discovered and aspirated. The FNA smears strongly suggested that the cells represented metastatic renal tumor. The "oncocytoma" from 1985 was reclassified as ChRCC (Fig. 40-12A,B). Also, **oncocytomas may be associated with conventional RCC** (Klein and Valensi, 1976; Fromowitz and Bard, 1990).

Figure 40-13 Oncocytoma. *A.* Gross appearance of an oncocytoma. The tumor is often subcapsular, uniformly tan to mahogany brown, and may show blood-filled microcysts but no necrosis or hemorrhage. *B.* Histology of the oncocytoma: very large uniform cells with dense, pink, granular cytoplasm and disproportionately small, uniform nuclei. The cells are supported by delicate fibroconnective tissue. *C,D.* Oncocytomas in aspiration biopsies.

Note the faintly granular, eosinophilic granular cytoplasm and small nuclei.

Cytology

As first described by Rodriguez et al (1980), the FNA smears contain a **uniform population of large eosinophilic granular cells (oncocytes)** that are either isolated or form small, loose aggregates. The **cell borders** are well defined and the **nuclei** are quite **small and round**, with finely granular chromatin and inconspicuous, **tiny nucleoli** (Fig. 40-13C,D). **Although oncocytic-type cells** may also occur in the **chromophobe or granular cell types of conventional RCC**, these two lesions are characterized by significant **nuclear abnormalities, including large nucleoli that are not observed in oncocytoma** (Wiatrowska and Zakowski, 1999) (see Table 40-5).

Collecting Duct Carcinoma (CDC)

Collecting duct carcinomas (also known as **carcinomas of the ducts of Bellini**) are **very rare, aggressive** renal tumors. They account for less than 1% of malignant renal tumors, and are thought to arise within the **collecting ducts of the renal medulla**. Cytogenetic findings support the concept that the CDC is a distinct entity (Schoenberg et al, 1995) (see Table 40-2). CDCs are usually located in the **medulla of the kidney, adjacent to the renal pelvis**, and tend to develop in **younger patients** with symptoms of hematuria, pain, and weight loss, and the presence of a palpable mass. Fifty percent of these patients have **metastatic disease** to the lymph nodes, bone, and viscera at the time of diagnosis.

In tissue sections, the tumors are composed of **neoplastic ducts and tubules** lined by clearly malignant cells, some

P.1477

of which have granular cytoplasm (Fig. 40-14A), and of nests of clear cells embedded in fibroblastic stroma that is sometimes very dense. Mucin may be present in some of the glandular structures. Adjacent **renal tubules** may show dysplastic changes (Kennedy et al, 1990), and **psammoma bodies** may be present.

Figure 40-14 Histology of collecting (Bellini) duct carcinoma. *A.* Neoplastic ducts/tubules are lined by cancer cells with eosinophilic cytoplasm and large, hyperchromatic nuclei with prominent nucleoli. Mucin vacuoles may be seen. *B.* Cell block of FNA of medullary carcinoma. The microscopic presentation is not specific.

Cytology

Because they are located in the vicinity of the renal pelvis, CDCs may be recognized in **urinary sediment** (Mauri et al, 1994; Caraway et al, 1995), **retrograde brushings** of the renal pelvis (Zaman et al, 1996), and **transcutaneous FNAs** (Layfield, 1994; Caraway et al, 1995; Ono et al, 2000). The **neoplastic cells** are **medium-sized** and uniform, with **scanty eosinophilic granular or vacuolated cytoplasm, very large hyperchromatic nuclei, and very large multiple nucleoli** (Layfield, 1994; Caraway et al, 1995). The cancer cells occur singly or form large aggregates, some of which may have a **papillary configuration**. Caraway et al (1995) reported the presence of **psammoma bodies** in about one half of their patients. It is debatable whether the cytologic findings, although clearly consistent with a malignant tumor, are specific for CDC. In several of the reported cases, a diagnosis of poorly differentiated RCC was rendered first. The **location of the tumor** should be considered in the diagnosis. It may also be noted that none of the other renal tumors with granular cytoplasm have equally large nuclei (see Table 40-5).

Medullary Carcinoma

Medullary carcinomas represent a unique group of rare, highly aggressive, and nearly always fatal renal tumors that almost exclusively occur in **young patients with sickle-cell trait or anemia** (Davis et al, 1995). These tumors **share many morphologic features with CDC** and are composed of **cells with markedly abnormal, large, irregular nuclei and prominent nucleoli** arranged in **solid nests and irregular tubules**. A **microcystic growth pattern** is also common. The stroma is composed of dense connective tissue that is infiltrated by inflammatory cells.

A case report of FNA of a medullary carcinoma was recently published (Qi et al, 2001). The diagnosis of malignant renal tumor was established in a 14-year-old African-American boy with disseminated metastases and sickle cell trait. We have not seen an FNA smear from such a tumor. However, we recently observed a **positive urine cytology** and needle core biopsy from a 27-year-old African-American patient with disseminated medullary carcinoma. In the absence of appropriate clinical context (i.e., a young male with sickle cell trait), this specific diagnosis would be impossible to establish.

CARCINOMA OF THE RENAL PELVIS

For the most part, tumors of the renal pelvis are **morphologically identical to urothelial tumors of the bladder**, and they may be **papillary** or **nonpapillary**. These tumors often precede or follow similar tumors of the bladder. **Squamous carcinoma** and **adenocarcinoma** are rare (Bennington and Beckwith, 1975; Davis et al, 1987; Koss et al, 1992; Koss, 1995). Tumors of the renal pelvis frequently cause **hematuria and ipsilateral pain**. **Urine cytology may contribute to the detection and diagnosis of many of the high-grade tumors, but is not helpful in diagnosing well-differentiated, low-grade papillary tumors** (Koss, 1992, 1995) (see Chap. 23).

Occasionally in imaging studies, carcinomas of the renal pelvis cannot be differentiated from tumors of the renal parenchyma. In such cases, **transcutaneous FNA** may contribute to the diagnosis. The **uteroscopically guided retrograde FNA** is technically extremely difficult. The FNA smears reflect the histology of the tumors.

Cytology

The aspirates of **low-grade papillary urothelial tumors** may show papillary fronds that must be differentiated from

P.1478

PRCC. The make-up of these fronds, which usually display **umbrella cells** on the surface, is discussed at length in Chapter 23.

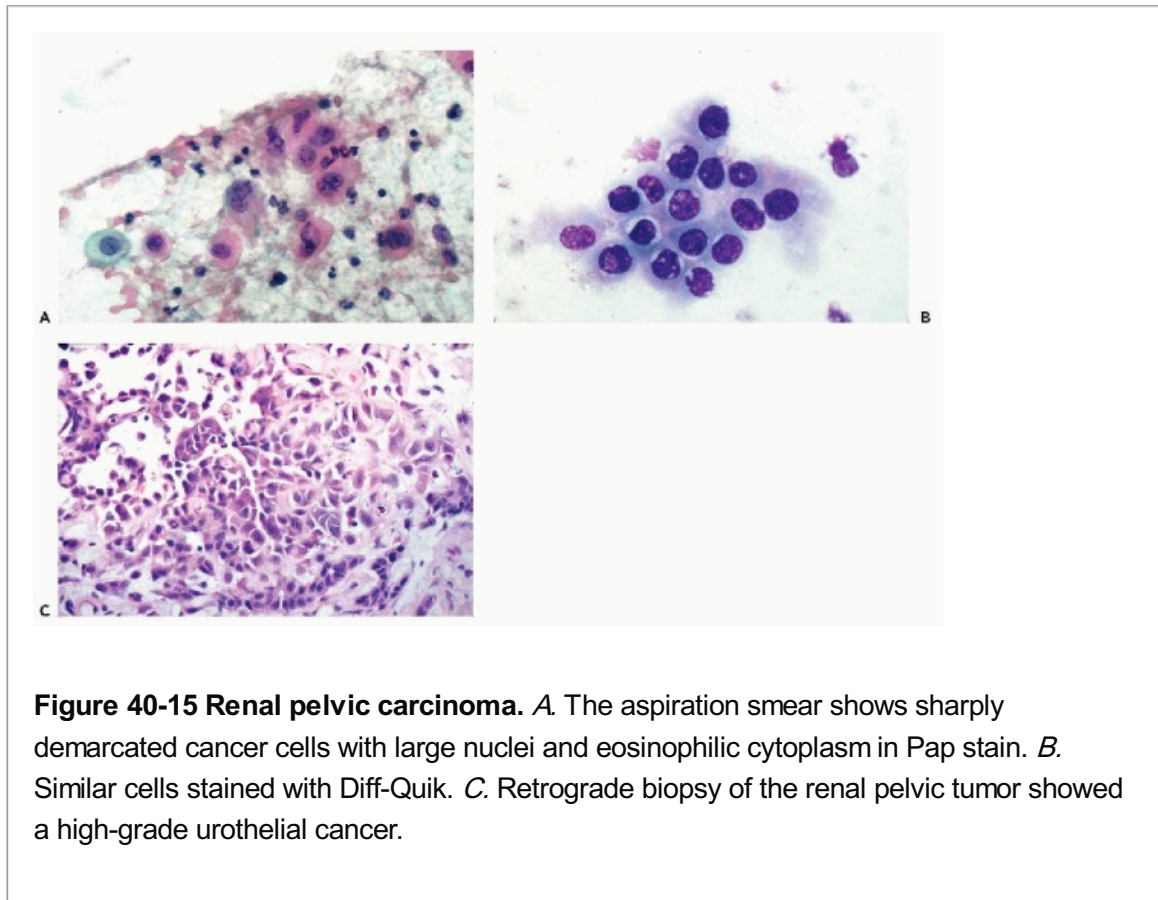

Figure 40-15 Renal pelvic carcinoma. *A.* The aspiration smear shows sharply demarcated cancer cells with large nuclei and eosinophilic cytoplasm in Pap stain. *B.* Similar cells stained with Diff-Quik. *C.* Retrograde biopsy of the renal pelvic tumor showed a high-grade urothelial cancer.

High-grade urothelial carcinoma and its squamous or glandular variants yield obviously malignant cells, either dispersed or arranged in loose clusters (Koss et al, 1992; Koss, 1995). Urothelial carcinoma cells usually have a **sharply demarcated homogeneous cytoplasm** and large, compact, **hyperchromatic nuclei** (Fig. 40-15). These cells differ significantly from RCC cells and are recognizable. Other tumor types shed cells as described in Chapter 23.

MALIGNANT RENAL TUMORS IN CHILDREN

Only about 500 malignant renal tumors occur annually in children in the United States (Beckwith, 1983); therefore, most pathologists have only limited experience with these tumors.

Wilms' tumor is by far the most common, accounting for 85% of cases. Three other types of pediatric renal tumors—**benign mesoblastic nephroma**, **malignant clear cell sarcoma**, and **rhabdoid tumor**—are exceedingly rare.

Wilms' Tumor (Nephroblastoma or Carcinosarcoma)

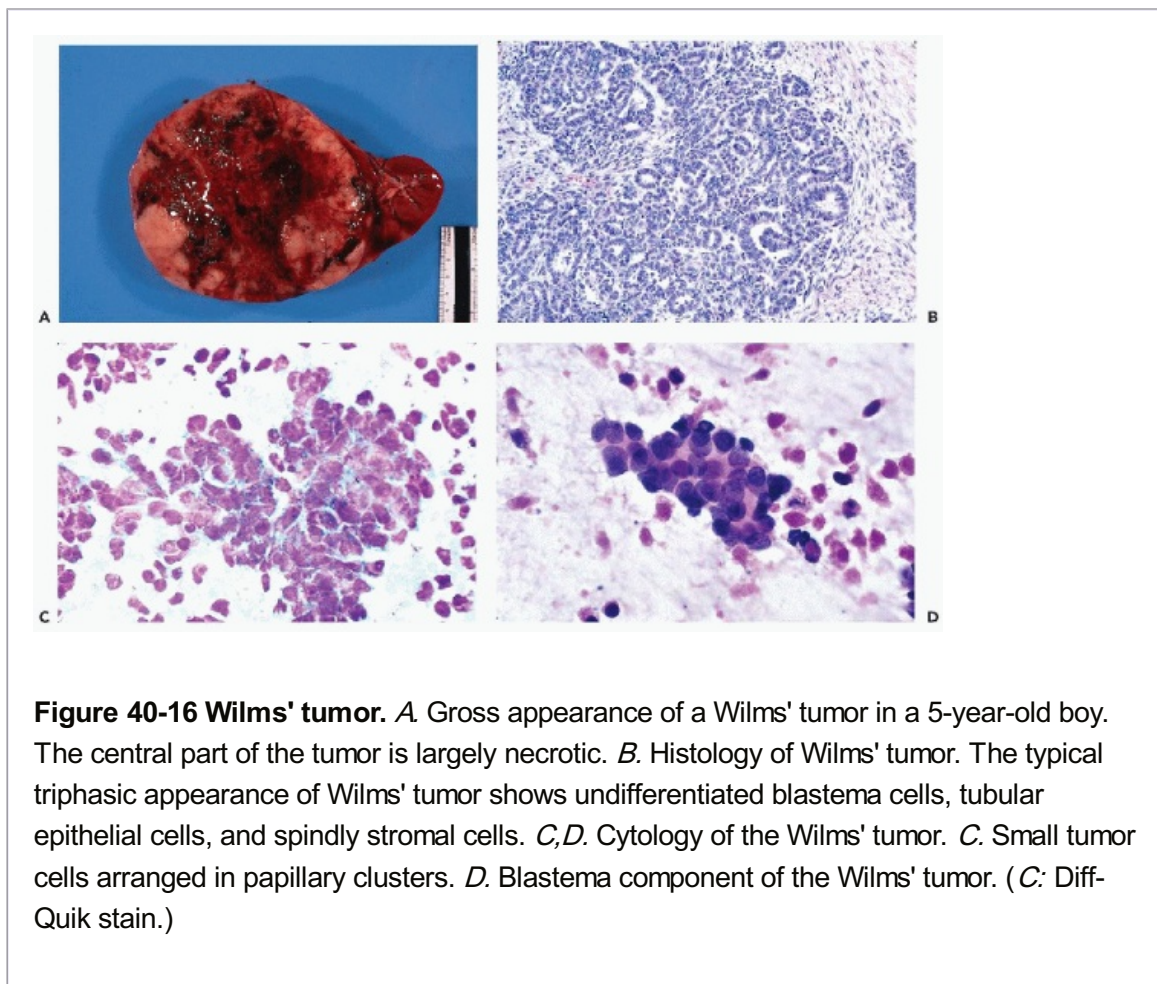

Wilms' tumor occurs mainly in **infants and children** younger than 10 years of age (Weeks et al, 1991). Rarely, the tumor occurs in **adolescents and adults** (Kilton et al, 1980; Wong and Zaharopoulos, 1983; Berkley et al, 1990; Li et al, 2002). Similar tumors may occasionally occur in extrarenal locations (Waingankar et al, 1995; Babin et al, 2000) and have been found in the uterus, cervix, ovary, and testis (Gillis et al, 1994).

Children with this tumor are usually seen because of a **palpable but asymptomatic abdominal mass** that was discovered by a parent, or, rarely, because of complaints from the child (Fig. 40-16A). Approximately 25% of these patients have distant metastases (usually to the lymph nodes, lung, and liver) when first seen. Modern-day **chemotherapy** and radiotherapy preceding or following **surgical resection** may cure 85% to 90% of Wilms' tumors, even if the tumor is disseminated. A small subgroup of **anaplastic Wilms' tumors** (see below) has an unfavorable prognosis.

Some of these tumors may be recognized in **voided urine sediment** (see Chap. 23). **FNA** is relatively rarely utilized prior to surgery because in most instances the diagnosis is fairly obvious clinically and radiologically, and because a larger sampling is required to assess favorable vs. unfavorable histologic patterns. Paradoxically, open or needle core biopsy may upstage a stage 1 tumor to stage 2 (Beckwith, 1998).

Ellison et al (1996) listed the **indications for FNA** that may be used as a diagnostic modality when there is **uncertainty as to the identity of the tumor, or to confirm unresectable or bilateral tumors, and the presence of metastases**.

P.1479

Histology

Wilms' tumors are composed of **three fundamental elements**: (1) an **embryonal epithelium that mimics tubules and glomeruli**, and is surrounded by (2) **undifferentiated small malignant cells, known as the blastema**; and (3) **stromal elements of a spindle cell sarcoma, or sometimes a rhabdomyosarcoma, with striated muscle cells** (see Fig. 40-

16B). The three tissue types occur in various proportions and are arranged in a haphazard fashion. Other epithelial types, such as glandular or squamous epithelium, may occur. A small subgroup of these tumors is anaplastic, containing cancer cells with huge hyperchromatic nuclei and numerous, often multipolar mitotic figures (Faria et al, 1996). The epithelial elements of these tumors stain for keratin, whereas vimentin stains stromal elements. Stains for desmin, S100, and endocrine markers are usually negative. Ellison et al (1996) reported that DNA ploidy in three such tumors was near-diploid.

Cytology

The FNA smears of Wilms' tumor are usually cellular. The three elements of the tumor are not always present. The most common pattern is that of a **small cell malignant tumor, reflecting the blastema cells** (Fig. 40-16D). These small cells with relatively **large, hyperchromatic nuclei** and a very **scanty, usually indiscernible rim of cytoplasm**, are either dispersed or form loosely structured aggregates. The somewhat larger **epithelial cells, which form three-dimensional tubules or spherical aggregates that mimic glomeruli**, are present in approximately one half of the cases (Fig. 40-16C). At the periphery of the clusters, the epithelial cells usually appear **cuboidal or columnar**, and their nuclei are large and hyperchromatic.

Spindly stromal cells, some of which have cytoplasmic cross-striations, are also present in about half the cases (Quijano and Drut, 1989; Akhtar et al, 1989b; Dey et al, 1992; Koss et al, 1992; Hazarika et al, 1994; Koss, 1995).

In an FNA of the **uncommon anaplastic form of Wilms' tumor**, Drut and Pollono (1987) observed obvious **large, bizarre cancer cells with large nuclei and nucleoli** in the presence of some of the other tumor elements. We have not observed such a case.

The **differential diagnosis** of the common type of Wilms' tumor includes other **small-cell malignant tumors of childhood**, such as **neuroblastoma**, wherein cells form **rosettes and neurofilaments**; **Ewing's sarcoma**, which is characterized by tumor cells that contain **glycogen** and stain with **periodic acid-Schiff (PAS)**; **embryonal rhabdomyosarcoma**,

P.1480

which is recognizable in the presence of **strap cells with cytoplasmic cross-striations**; and **non-Hodgkin's lymphoma**, which is recognizable because of **dispersed tumor cells with nuclear abnormalities**. Except for the rare striated, elongated cells of rhabdomyosarcoma, none of the other features occur in Wilms' tumor. A detailed description of the tumors included in the differential diagnosis is provided in the appropriate chapters.

Wilms' Tumor in Adults

Wilms' tumor in adults is a rare event. Several case reports of cytologic findings in FNA have been published (Wong and Zaharopoulos, 1983; Berkley et al, 1990; Koss et al, 1992; Li et al, 2002). As in infants and children, the dominant element is **small blastema cells**; however, Li et al (2002) also observed **epithelial and stromal elements** of the tumor. They described cytogenetic findings in one case, and reported multiple chromosomal abnormalities.

In a case described by Koss (1995), a tumor observed in the kidney of a 54-year-old man was thought to represent renal carcinoma. A chest radiogram disclosed multiple small lung metastases. The FNA disclosed small tumor cells that occurred singly and in loosely structured small clusters (Fig. 40-17). The differential diagnosis included **metastatic small-cell carcinoma and malignant lymphoma**. A renal tissue biopsy disclosed a small-cell tumor, possibly a Wilms' tumor. The patient responded dramatically, although only temporarily, to the

chemotherapy regimen used to treat pediatric Wilms' tumors.

Rhabdoid Tumor

The rhabdoid tumor is an exceedingly rare renal tumor that occurs predominantly in **infants and young children**. The tumor is highly aggressive and has a poor prognosis (Weeks et al, 1989, 1991). The histogenesis is unknown. Rhabdoid tumors have now been reported in all age groups and in sites other than the kidney (Parham et al, 1994; Fanburg-Smith et al, 1998; Ogino et al, 2000).

Figure 40-17 Adult Wilms' tumor. *A.* Aspirate of a renal mass in a 54-year-old man. Clinically, the lesion was suspected of being a renal carcinoma. The smear pattern shows small cancer cells forming loosely structured clusters. *B.* The biopsy of the tumor disclosed the neoplasm composed of nests of small cells, interpreted as adult Wilms' tumor. Although the patient had multiple metastases, he did well on conventional Wilms' tumor therapy, but died of disease about a year and a half later.

In **tissue sections**, the tumor is composed of a single population of cells that may vary in size and configuration from round or oval to spindly. The characteristic feature of these tumors is the presence of **large, eosinophilic cytoplasmic inclusions** that displace the nucleus of the cell to the periphery. On electron microscopy, the inclusions are composed of **intermediate filaments**. There is no evidence that the cytoplasmic inclusions represent an accumulation of myoglobin, but it is the appearance of myoglobin that gave the tumor its name. Similar cytoplasmic inclusions that stain with an antibody to myoglobin may be observed in cells of **rhabdomyosarcoma**. From time to time, **similar cytoplasmic inclusions may be observed in other tumors**, including undifferentiated large-cell lung cancer. To our knowledge, there is only one published description of the **cytologic findings in FNA biopsies** of rhabdoid renal tumors. In three patients, Akhtar (1991) observed **large polygonal cells with abundant dense pink cytoplasm, large intracytoplasmic eosinophilic inclusions, and large nuclei with macronucleoli**.

Clear Cell Sarcoma of Kidney

Clear cell sarcoma of the kidney, also known as **bonemetastasizing renal tumor**, is a rare, highly aggressive tumor that occurs in young children (average age = 3 years). **Metastases to the skeleton**, particularly the **skull**, are known to occur.

In **tissue sections**, the tumors may show **several histologic patterns**. Tumors with the

classic pattern are composed of **small cells with clear cytoplasm**. The **nuclei** are small and often show prominent **grooves**. Other tumors may form **tubules** and thus mimic Wilms' tumor. **Spindle-cell, epithelioid, and myxoid patterns** may also occur, and the latter appears deceptively innocuous (Beckwith, 1999).

Information regarding the **cytologic presentation** of this

P.1481

tumor in FNA samples is scanty and limited to a few case reports. In smears, Akhtar et al (1989), Drut and Pomar (1991), and Krishnamurthy and Bharadwaj (1998) observed **bland, polygonal, stellate, or spindle-shaped cells** with variable amounts of cytoplasm, occurring singly and in clusters. Perhaps the most characteristic feature of these tumors, as stressed by Krishnamurthy and Bharadwaj (1998), was the appearance of the **nuclei, which showed deep nuclear indentations and grooves**. Other observers reported monotonous nuclei with fine chromatin and sometimes small nucleoli. It is quite evident that the cytologic experience with these tumors is too limited to allow for the formulation of a reliable cytologic picture of diagnostic value (see also Chap. 36).

Mesoblastic Nephroma

Mesoblastic nephroma is a rare **congenital renal tumor that occurs in infants** (3 months of age or less), usually in the medulla of the kidney. **Histologically**, the **classic pattern** of this tumor in tissue sections consists of **spindly cells, mimicking a leiomyoma**. An **atypical pattern**, mimicking a small-cell malignant tumor with numerous mitoses, is also recognized. In general, this tumor has an excellent prognosis, but it is also capable of invading the kidney and metastasizing, particularly when it is observed in infants older than 3 months and displays the atypical pattern (Schlesinger et al, 1995).

The **FNA cytology** of this tumor has been described by Dey (1992) and Kaw (1994) as showing a scant amount of material in a clean background. The **spindly cells of the classic form of the tumor** appear in **bundles** or as single cells with **minimal nuclear atypia**. There is no information on the cytology of the atypical form of this tumor.

PRIMARY RENAL SARCOMAS

Except for the rhabdoid tumors and clear cell sarcomas observed in children (see above), most other primary sarcomas occur **in adults** and constitute approximately 1% of the malignant neoplasms of the kidney. The most common of these tumors are **leiomyosarcomas, rhabdomyosarcomas, hemangiopericytomas, and liposarcomas** (Farrow et al, 1968; Brodsky and Garnick, 1989). Most of these tumors originate in the **renal capsule, or are subcapsular** and may compress the kidney but not necessarily invade it. **Liposarcoma** may originate in the **perirenal fat**. Some sarcomas occur in the renal hilum, where blood vessels, lymphatics, and adipose tissue cluster together.

It may be difficult to distinguish primary spindle cell sarcomas from the spindle (sarcomatoid) cell variant of conventional RCC (see Fig. 40-9C,D), particularly in the case of leiomyosarcoma. Immunochemical stains are a useful diagnostic aid. Farrow et al (1968) also described a few **cases of primary malignant non-Hodgkin's lymphomas** (Fig. 40-18).

The **cytologic presentation** of these tumors in FNA is similar to that of sarcomas and lymphomas of other sites, and is described in Chapters 31 and 35.

Figure 40-18 Malignant lymphoma showing single cells with scanty cytoplasm and nuclear contour abnormality. (Diff-Quik stain.)

METASTATIC TUMORS

The kidney is occasionally the site of cancers that have metastasized from other organs, such as the **lung** (Fig. 40-19), **breast, colon, pancreas, and stomach**. Less commonly, **thyroid carcinomas and melanomas** may also metastasize to the kidney. **For the most part, lymphomas are metastatic from other sites**, although they can also originate in the kidney (see above). **Malignant tumors** of the **adrenal** may directly invade the kidney. **Kidney-to-kidney** metastases also occur. Most of this information is gathered at the autopsy table, and there is limited information on the cytology of these events (Petersen, 1986).

In a series of **136 positive renal FNA samples**, Gattuso et al (1999) observed **28 (21%) metastatic tumors**, a surprisingly high number. In order of frequency, the most common metastatic tumors were of **lung** origin, followed by **malignant lymphomas, hepatocellular carcinomas, breast, pancreas, and uterine cervix**.

It is difficult to recognize metastatic cancer in renal **FNA cytology**. The key is to recognize a **cell pattern or cell features that are “not of renal origin.”** Considering the vast panorama of cell abnormalities in renal tumors described in this chapter, success is uncertain and requires not only cytologic expertise but also knowledge of the **clinical setting** of the aspiration procedure. As a rule of thumb, if an adult patient shows evidence of other metastases, the renal lesion is bilateral, and the smear shows a pleomorphic large-cell tumor or undifferentiated small-cell tumor, the possibility of metastases must be considered.

RESULTS OF RENAL ASPIRATION BIOPSIES

Given the appropriate indications, renal FNA can be one of the most successful applications of this technique. The

P.1482

recognition and treatment of cystic lesions and the diagnosis of renal cancer are reliable diagnostic procedures in experienced hands.

Earlier papers reported that **FNA biopsy of malignant tumors of the kidney had a sensitivity of about 85%, and a specificity of about 98%** (Helm et al, 1983; Orell et al, 1985; Pilotti et al, 1988). This is in keeping with our experience (Koss et al, 1992), and approximately similar values have been cited in recent reviews of this subject (Truong et al, 1999; Zardawi, 1999).

False-negative diagnoses usually relate to inadequate material as a result of necrotic, hemorrhagic, or cystic tumors, or a failure to sample small tumors (Holm et al, 1975; Murphy et al, 1985; Orell et al, 1985; Pilotti et al, 1988). Occasional **false-positive** diagnoses have been reported in cases of chronic inflammation, infarcts, polycystic kidney disease, cysts, hematoma, angiomyolipomas, and other benign neoplasms (Helm, 1983; Juul, 1985; Murphy, 1985; Orell, 1985; Pilotti, 1988; Haubek, 1991; Silverman, 1991; Torp-Pedersen, 1991; Horwitz, 1994).

There are **limitations in the subclassification of some RCCs**. At times it may be difficult or impossible to distinguish between PRCC and the pseudopapillary variant of conventional RCC, or between ChRCC and oncocytoma or other tumors with granular cell cytoplasm (see Table 40-5). In debatable cases, it is prudent to report these entities descriptively, indicating the differential diagnosis. So long as the tumor is resectable, precise cytologic subclassification of renal tumors is academic in most cases.

THE ADRENALS

Only after CT was introduced in the early 1980s could FNA of adrenal lesions be performed. Work-ups for lung cancer and sometimes for breast cancer included CT scans of the chest and upper abdomen, leading to the discovery of **asymptomatic unilateral or bilateral adrenal nodules**. The term **incidentaloma** was coined to describe these observations (for recent summaries see Graham and McHenry, 1998; Kievit and Haak, 2000; Porcaro et al, 2001). **The issue at hand was further identification of the nature of these nodules as either benign or malignant, and, if malignant, whether the tumor was primary or metastatic.** FNA became the method of choice for identifying the nature of occult adrenal masses. Magnetic resonance imaging (MRI) is occasionally helpful in identifying adrenal lesions (Tung et al, 1989). It is possible that future refinements in **positron emission tomography (PET)**, a noninvasive technique for measuring metabolic activity, will be helpful in distinguishing benign

from malignant adrenal nodules.

The diagnosis of **occult adrenal metastases** is particularly important because it may significantly **modify the therapeutic approach to the primary cancer**. However, shortly after the FNA procedure was initiated, it became clear that a large number of **radiologically suspicious, asymptomatic adrenal nodules were benign**. In an unpublished series of cases seen by the author in 1984, 11 of 23 FNA samples of adrenal nodules were benign. Other investigators had similar experiences. For example, in a number of studies involving patients with cancer (particularly lung cancer), approximately one half of all adrenal masses were benign at biopsy (Oliver et al, 1984; Ettinghausen and Burt, 1991; Hoda et al, 1991; Gilliams et al, 1992; Saboorian et al, 1995). Consequently, the **recognition of benign adrenal lesions by FNA** became as important as the recognition of metastatic disease because it spared the patient an unnecessary abdominal operation (or the now widely used **laparoscopic adrenalectomy** which is less traumatic for the patient).

Previously published data suggest that a significant percentage of people over the age of 50 harbor benign adrenal lesions, either hyperplasia or adenoma (Commons and Callaway, 1948; Spain and Weinsaft, 1964; Russel et al, 1972; Hedeland et al, 1968; Abecassis et al, 1985). Autopsy review studies have shown that approximately 2% to 8% of the population have an occult adrenal mass (Hedeland et al, 1968;

P.1483

Abecassis et al, 1985; Grizzle, 1988), and an even higher incidence has been reported in autopsy series of hypertensive patients (Sharma et al, 1958).

INDICATIONS FOR FNA

Despite their small size, the adrenals harbor a disproportionate number of metastatic malignant tumors. Therefore, the **confirmation of a suspected metastasis is the primary indication for an FNA biopsy**. As described above, this search will uncover a large proportion of **incidental benign adrenal lesions** and **occasionally primary malignant tumors of the adrenal**.

Figure 40-20 Histology of normal adrenal gland. *A.* In this low-power view, there is a clear-cut demarcation of the cortex and medulla. The three zones of the cortex are also apparent. The lighterstained and wide zona fasciculata is in the middle. *B.* The zona reticularis of the cortex with relatively smaller eosinophilic lipid-poor cells interfacing medulla. The medulla (*left*) is composed of cell balls and cords with intensely basophilic cytoplasm.

Table 40-6 lists the space-occupying lesions of the adrenal that may be targeted for FNA biopsy.

SYNOPSIS OF ANATOMY AND HISTOLOGY

The adrenal glands are small, triangular, paired retroperitoneal **endocrine organs** that are located on the superiomedial aspects of each kidney. In adults, each gland weighs about 4 g and measures about 5 × 3 × 1 cm. In infants, the adrenal glands are disproportionately large in relation to the kidneys.

The adrenal glands have dual embryologic origin. The **mesoderm-derived cortex** is bright yellow and makes up to 90% of the gland, whereas the **ectoderm or neural crest-derived medulla** is waxy white and forms the soft inner core. **The cortex and medulla are functionally and histologically different** (Fig. 40-20A).

The **adrenal cortex** is composed of polygonal cells with eosinophilic cytoplasm arranged in **three zones**. The narrow outermost layer is the **zona glomerulosa**, which is composed of **large lipid-laden foamy cells** with small round nuclei in glomeruloid (rounded) clusters. The thick middle layer, or the **zona fasciculata**, is composed of similar but **slightly larger lipid-laden cells** arranged in cords. The inner-most layer of the cortex, the **zona reticularis**, is thin and composed of **smaller** eosinophilic, finely granular, **lipid-poor cells** (Fig. 40-20B).

The **medulla** is a part of the **sympathetic nervous system** and forms the small **core of the adrenal gland**. The cells of the adrenal medulla are arranged in spherical aggregates known as **Zellballen** (German for cell balls). The cells are **pleomorphic, polygonal, fusiform, or ovoid**, and have a high N/C ratio. They have intensely **granular basophilic cytoplasm** and **nuclei with a coarse chromatin pattern**, as commonly seen in neuroendocrine cells (Fig. 40-20B).

P.1484

The cells of the adrenal medulla are **argyrophilic** and stain with Grimelius silver stain.

TABLE 40-7 ENDOCRINE FUNCTION OF THE ADRENAL GLANDS IN HEALTH AND DISEASE			
Zones	Primary Hormones	Cardinal Functions	Hyperfunction
Cortex			
Zona glomerulosa	Aldosterone	Salt and water balance	Conn's syndrome
Zona fasciculata	Cortisol	Glucose and carbohydrate metabolism	Cushing's syndrome
Zona reticularis	Estrogens and androgens	Extragonadal source of sex hormones	Adrenogenital syndrome
Medulla	Adrenaline	Blood pressure regulation	Hypertension

Table 40-7 lists the primary hormones produced by the adrenal glands in health and disease.

CYTOLOGY OF NORMAL ADRENAL GLANDS

A normal adrenal gland is sometimes inadvertently aspirated when a kidney lesion located in the upper pole is sampled. The best representation of benign adrenal cortical cells is seen in aspiration smears of **adrenal cortical hyperplasia or adenoma**.

Well preserved adrenal cortical cells are approximately **equal in size to hepatocytes, which they may resemble** because of **faintly vacuolated or granular eosinophilic cytoplasm and small, vesicular nuclei** (Fig. 40-21A,B). In Diff-Quick stain, the **cytoplasmic lipid droplets** are obvious in the form of clear spaces in the cytoplasm and vacuoles in the background (Fig. 40-21C). In fortuitous cases, the cells form approximately **spherical aggregates** that resemble the structure of the zona glomerulosa of the cortex (Fig. 40-21A). However, the cells derived from the zona glomerulosa and fasciculata are identical. Theoretically, the cells from the zona reticularis should contain **golden-brown lipofuscin pigment** (Katz et al, 1984; Nguyen, 1987). We have not been able to identify such cells with certainty.

More often, however, particularly in air-dried smears, the cortical cells are stripped of their fragile cytoplasm and appear as **perfectly spherical and mostly uniform bare nuclei** that are slightly larger than background erythrocytes and have **granular, evenly distributed chromatin, and small but distinct nucleoli**. In the disintegrating cytoplasm, lipid vacuoles may be observed (Fig. 40-21B,C). It has been alleged that the stripped nuclei mimic small, round cell malignant tumors (Min et al, 1988; Suen and McNeely, 1991; Wadih et al, 1992). With reasonable experience, it is easy to recognize the distinctly benign configuration of these nuclei. The cells of **normal adrenal medulla** are rarely encountered in aspirates of adrenal cortical lesions. They are illustrated in a touch-preparation in Figure 40-21D. Note that these cells have nuclei of variable sizes and visible nucleoli. The cytoplasm is poorly preserved and granular. A few such cells may occasionally be observed in aspirates of benign cortical adenomas, and may be mistaken for cancer cells. However, the sparse population of cells and the low level of nuclear abnormalities usually prevents such a diagnostic error.

DISEASES OF THE ADRENAL CORTEX

Benign Lesions

Adrenal Cysts

Adrenal cysts are uncommon; however, the detection rate for such cysts as a result of CT and MR imaging has increased dramatically. Most adrenal cysts are **unilateral, occur more often in women than men**, and are classified under four categories as described below:

- **Pseudocysts** are most common and are probably secondary to adrenal hemorrhage. Such cysts have no epithelial lining.
- **Endothelial cysts** are simple cysts of vascular origin, and are most often miniature lymphangiomas with an endothelial lining.
- **Retention cysts, congenital cysts, or cystic adenomas** may have an epithelial lining.
- **Parasitic cysts** are usually of **echinococcal** etiology.

Cytology

FNA aspirations of benign adrenal cysts may yield small amounts of **bloody, turbid, clear**

yellow, thin, or viscous fluid (Nosher et al, 1982; Tung et al, 1989). Generally, the smears are **sparsely cellular** with a variable number of **foamy macrophages** and a few leukocytes, not unlike simple renal cysts (Gleeson and McMullin, 1988; Tung, 1989). The precise type of cysts cannot be determined on cytologic examination of the fluid. Rarely, the **bloody cyst fluid** may occur in **cystic metastatic carcinoma** (Gaffey et al, 1990).

Adrenal Myelolipoma

The myelolipoma is an uncommon lesion composed of **mature fat containing normal hematopoietic cells**. It may appear as a unilateral **adrenal or retroperitoneal mass** that may be palpable, causing nonspecific symptoms, or may be discovered accidentally during an abdominal CT scan for an unrelated disease (Dunphy, 1991; Sharma MC et al, 1997).

One is usually alerted to the diagnosis of myelolipoma

P.1485

in an FNA smear by finding **megakaryocytes and then searching for immature myeloid cells** (Fig. 40-22). The mature adipose tissue may be difficult to see in alcohol-fixed smears (Evans et al, 1990). Similar **hematologic features** may be observed in **extramedullary hematopoiesis in the liver or spleen**. Rarely, **foci of hematopoiesis** may occur in **cortical adenomas**.

Figure 40-21 Cytology of normal adrenal gland. *A.* Normal adrenal cortical cells forming clusters (from a case of adrenal cortical adenoma). Note the abundant, eosinophilic, granular cytoplasm and small, spherical nuclei). *B.* Well preserved adrenal cortical cells. Note the cytoplasmic lipid vacuoles, occasional binucleation, one larger nucleus, and perfectly round nuclear contours. *C.* Adrenal cortical cells in Diff-Quik stain. Cytoplasmic lipid droplets are obvious in the remnants of the disintegrating cytoplasm. Note the striking nuclear uniformity. *D.* Touch-preparation of adrenal medulla. The nuclei are pleomorphic, and the cytoplasm is granular and basophilic.

Figure 40-22 Adrenal myelolipoma. A single megakaryocyte (*top, left*), immature myeloid cells, a few islands of adrenal cortical cells, and mature fat cells are shown (cell block of FNA).

Inflammatory Lesions

Mycobacteria, fungi, and viruses that affect the adrenals are virtually always a consequence of systemic infections, are most commonly observed in immunosuppressed patients, and are usually diagnosed at autopsy. However, there have been scattered reports of **histoplasmosis** (Anderson et al, 1989; Valente and Calafati, 1989; Deodar and Sapp, 1997), and **cryptococcosis** (Walker et al, 1989; Powers et al, 1991; Takeshita et al, 1992) of the adrenal, as identified on FNA smears. For a description of these organisms, see Chapter 19.

The FNA aspiration biopsy of an **adrenal abscess** yields purulent and necrotic cellular debris (Wadih et al, 1992) and is not a diagnostic problem.

Congenital Adrenal Cortical Hyperplasia

Congenital adrenal cortical hyperplasia is the most common cause of **adrenogenital syndrome, which results in precocious virilization**. This disease, which occurs mainly in infants but sometimes in older children as well, is caused

P.1486

by a deficiency of 21-hydroxylase, an essential enzyme for the metabolism of cortisol. The adrenal cortex is markedly enlarged, but its **cellular components are not morphologically remarkable**. The diagnosis is based on clinical and laboratory findings (Lack, 1997).

Acquired Diffuse and Nodular Hyperplasia and Adenomas

A diffuse or nodular thickening of the adrenal cortex, and adrenal nodules are among the most common human tumors. According to recent estimates, they are found in at least 3% of persons above age 50 (Graham and McHenry 1998; Kirvit and Haak, 2000; Porcaro et al, 2001). Most of these lesions **cause no health problems whatsoever** and are often discovered incidentally (**incidentalomas**). However, a few may be associated with **endocrine disorders**,

and some represent **malignant adrenal tumors** (see below).

The anatomic **boundaries among adrenal cortical hyperplasia, nodular hyperplasia, and adenomas are not sharply defined, but are size-related**. The **smaller adrenal masses** are usually designated as hyperplasia or nodular hyperplasia; **larger nodules** are designated as adenomas. Such nodules usually occur in a background of bilateral adrenal nodularity (Dobbie, 1969; Silverman and Lee, 1989). The **typical cortical adenoma** is a well circumscribed, rarely encapsulated nodule composed of benign cortical cells 2-3 cm in diameter (Fig.40-23A). The cut surface is bright yellow. **Giant adrenal cortical adenomas**, measuring up to 10 cm in diameter, may exhibit areas of hemorrhage, cystic degeneration, and calcification.

In tissue sections, the adrenal cortical hyperplasias and adenomas are composed of cells similar to those of the normal zona glomerulosa or zona fasciculata, or both. On **scanning magnification**, the cells are arranged in an alveolar pattern with delicate stroma (Fig. 40-23B). At first glance they may have an uncanny **resemblance to the low-grade clear cell type of conventional RCC**, which explains why the term **hypernephroma** has been applied for many years to renal tumors (see above). The similarities end at higher magnification, which discloses perfectly benign adrenal cortical cells with no nuclear abnormalities (see Fig. 40-21). Occasionally, scattered enlarged nuclei may be observed in adenomas.

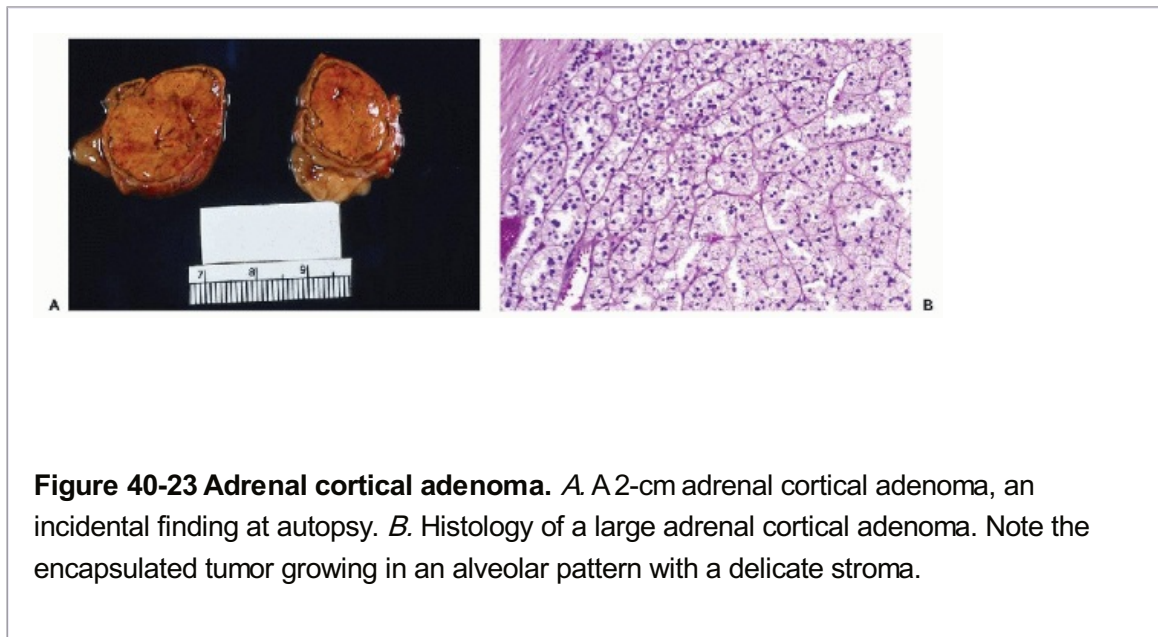

Figure 40-23 Adrenal cortical adenoma. *A.* A 2-cm adrenal cortical adenoma, an incidental finding at autopsy. *B.* Histology of a large adrenal cortical adenoma. Note the encapsulated tumor growing in an alveolar pattern with a delicate stroma.

Hormonally Active Lesions of the Adrenal Cortex

Although adrenocortical hyperfunction (**hyperadrenalism**) is quite rare, it produces some of the most fascinating clinical syndromes (see Table 40-7), and photographs of patients with these disorders, exhibiting the most dramatic physical alterations, have graced many endocrinology chapters in textbooks. Except for very brief descriptions of syndromes that are pertinent to the subject of this book, it is not within the scope of this chapter to describe the pathophysiology of hyperadrenalism. **Unfortunately, FNA of the adrenal is very rarely helpful in diagnosing these disorders.**

Cushing's syndrome, which is caused by **excessive glucocorticoid production**, is characterized by obesity, a moon face, muscle weakness, osteoporosis of the spine, hypertension, and diabetes. The syndrome may be caused by an adenoma of the adrenal, a

pituitary tumor, a hormone-producing cancer (paraneoplastic Cushing's syndrome), or drugs. The adrenal in Cushing's syndrome may show a broad variety of nonspecific changes, ranging from **atrophy to hyperplasia and adenomas, to the very rare adrenal cortical carcinoma (ACC)**. Cushing's syndrome may be associated with a rare form of nodular hyperplasia: **pigmented micronodular adrenal disease**. This is caused by **lipofuscin deposits** in the cells of the zona fasciculata, which result in brown-black discoloration of the adrenals (**black adenoma**). This abnormality occurs in a familial disorder known as **Carney's syndrome**, in which the patients have multiple abnormalities in addition to Cushing's syndrome (Shenoy et al, 1984; Carney et al, 1986).

Conn's syndrome, which is caused by **excessive aldosterone production**, causes an imbalance in the metabolism of potassium and sodium, and results in episodes of **weakness and hypertension**. It is usually associated with unilateral and **small adrenal cortical adenomas** (less than 2 cm in diameter) or with **cortical hyperplasia**. The adenoma cells have relatively small vesicular nuclei with small but distinct nucleoli (De Lellis, 1999). Some adenomas exhibit

P.1487

considerable **variation in nuclear size and shape**. Patients treated with the drug **spironolactone** may show **large eosinophilic cytoplasmic inclusions (spironolactone bodies) in some cells** (Cain et al, 1974; Kay, 1976; Neville, 1978).

Adrenogenital syndromes, caused by **excessive androgen production**, may cause **premature virilization in boys, and virilization and hirsutism in women**. The syndrome has a **broad variety of causes**, including **unremarkable small adrenal adenomas**. Adrenal cortical tumors, which cause virilization and sometimes feminization, are more likely to be malignant (Didolkar et al, 1981; Weiss, 1984; Desai and Kapadia, 1988; Venkatesh et al, 1989; Luton et al, 1990). FNA may be of value in the diagnosis of such rare cases (see below).

Cytology of Cortical Hyperplasia and Adenomas

FNA smears of the **normal adrenal cortex, diffuse or nodular cortical hyperplasia, and cortical neoplasia (functioning or not)** are essentially similar in appearance. They are **composed of normal cortical cells and their "naked" nuclei**, as described above and illustrated in Figure 40-21A-C. Occasionally, **a few of the nuclei** may show **enlargement** (see Fig. 40-21B) but no other abnormal features.

Wu et al (1998) also noted a "bubbly, vacuolated lipid background," which was clearly the result of disintegration of the cytoplasm (see Fig. 40-21C). FNA smears of **adenomas** occasionally may be more cellular, with **greater clustering of epithelial cells**, occasionally containing **central capillary vessels**. For all practical intents and purposes, the cytologic diagnosis of adrenal cortical adenoma must be supported by radiologic imaging data showing a well circumscribed nodule.

To our knowledge, the cytology of **black adenoma**, which is sometimes observed in Cushing's syndrome, has not been described.

The cytologic differential diagnosis of adrenal cortical hyperplasias and adenomas includes low-grade RCC, occasionally a **metastatic tumor**, and well-differentiated ACC. However, it may be difficult or impossible to recognize the latter in FNA smears (Heaston, 1982) (see below). **RCC** is readily identified because of its **abnormal nuclear features**, including the presence of **prominent nucleoli** and cell pleomorphism (see The Kidney section above). Almost without exception, the metastatic tumors show significantly **greater nuclear**

abnormalities compared to benign cortical lesions.

Malignant Cortical Lesions: Adrenal Cortical Carcinoma (ACC)

ACCs are **rare, highly malignant tumors** with an annual prevalence estimated at two to four cases per million (Beldegrun et al, 1986; Ross and Aron, 1990). The tumors can occur in both **adults and children**. Approximately half of all ACCs are **functional**, and usually produce **Cushing's syndrome** and/or evidence of sex steroid overproduction (Tang and Gray, 1975; Didolkar et al, 1981; Weiss, 1984; Desai and Kapadia, 1988; Venkatesh et al, 1989; Luton et al, 1990). Cortical carcinomas tend to be **large** (90% are >6 cm in diameter) and **bulky**, weighing more than 500 g. Also common are **necrosis, hemorrhage, and calcification** (Beldegrun et al, 1986; Cagle et al, 1986; DeLellis, 1999).

In **tissue sections**, cortical carcinomas show **alveolar, trabecular, or solid patterns of growth**, or a combination thereof. The degree of differentiation in the component cells varies significantly from **well-differentiated tumors mimicking cortical adenomas** (Fig. 40-24A) to tumors composed of completely **undifferentiated cancer cells of various sizes**, including **bizarre giant cells** (Fig. 40-24B). No reliable **histologic criteria** exist to distinguish adenoma from a well-differentiated carcinoma, except for **vascular invasion** and the presence of **metastases**, commonly involving the liver, lymph nodes, and lung. **Poorly differentiated tumors** showing marked cell pleomorphism, atypical mitoses, and invasion of capsule and vessels, are easy to classify as malignant.

It may be difficult to distinguish an ACC from a high-grade renal carcinoma.

Immunohistochemical stains for **EMA** (positive in RCC) and **synaptophysin** (positive in many ACCs) may be helpful. Adrenal cortical tumors are immunoreactive for inhibin and A103/Melan-A (Renshaw and Graeter, 1998).

Cytology

The FNA smears of cortical carcinomas are usually rich in cells. With a few exceptions, the FNA experience with these tumors is limited to high-grade malignant tumors (Zajicek, 1979; Levin, 1981; Zornoza et al, 1981b; Katz et al, 1984; Koss, 1992; Sharma et al, 1997). Therefore, in most cases the smear pattern is that of a **high-grade malignant tumor, whereas well-differentiated tumors are rarely seen**. This bias toward high-grade malignant tumor in cytologic material is presumably a result of clinical case selection for FNA.

The smears of **well-differentiated tumors** contain relatively **uniform tumor cells**, occurring either singly or in loose clusters, with **abundant, eosinophilic granular cytoplasm**, relatively **large, often eccentric, but uniform nuclei with a coarse chromatin pattern, and prominent nucleoli** (Fig. 40-24C). Cytoplasmic vacuole formation with high lipid content in the cytoplasm was described by Katz et al (1984), but this observation has not been confirmed by others. **Capillary vessels may be occasionally observed within the cell clusters**, a feature that is not uncommon in endocrine tumors. Sharma S. et al (1997) noted that **foci of anisonucleosis** may be observed among the monotonous population of tumor cells. The resemblance to the grade 2 or 3 granular cell variant of RCC is inescapable (see above). Sharma S. et al (1997) discussed at length the **differential diagnosis** between these two tumor types. Perhaps the most important difference is **cytoplasmic vacuolization**, which is present in RCC but not in cortical carcinoma. In the final analysis, clinical and imaging findings are critical to the correct diagnosis.

Poorly differentiated cortical carcinomas yield large anaplastic malignant tumor cells of

variable sizes, singly and in loose groups. Many of the large cells are **multinucleated**.

P.1488

The **nuclei** are very **pleomorphic** and contain **prominent nucleoli**. Abnormal **mitoses** can be seen (Fig. 40-24D). Such smear patterns are not specific, and may be observed in any poorly differentiated tumor with giant cells. Somewhat similar smear patterns may also occur in **pheochromocytoma** (see below).

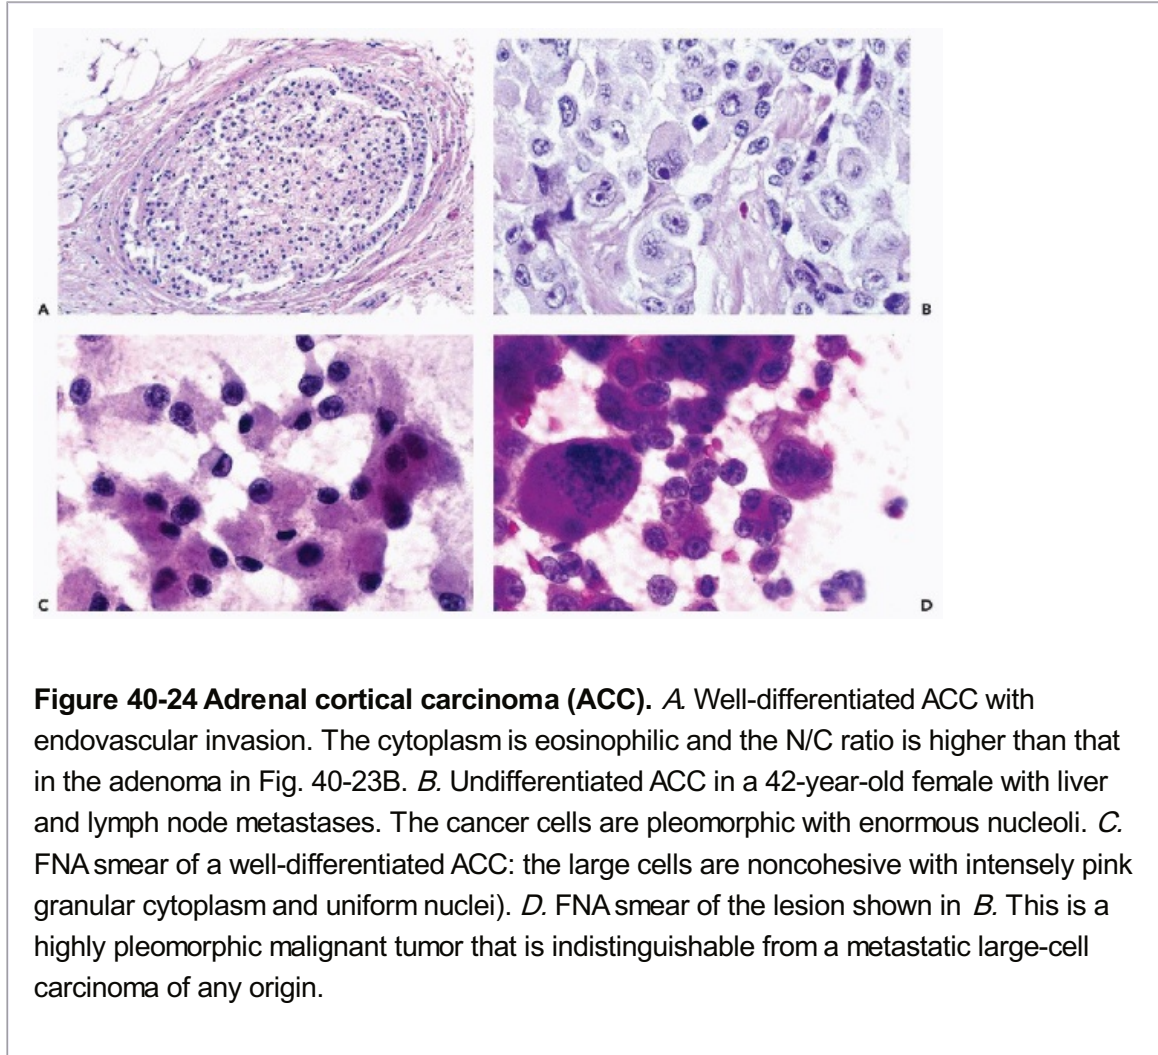

Figure 40-24 Adrenal cortical carcinoma (ACC). *A* Well-differentiated ACC with endovascular invasion. The cytoplasm is eosinophilic and the N/C ratio is higher than that in the adenoma in Fig. 40-23B. *B* Undifferentiated ACC in a 42-year-old female with liver and lymph node metastases. The cancer cells are pleomorphic with enormous nucleoli. *C* FNA smear of a well-differentiated ACC: the large cells are noncohesive with intensely pink granular cytoplasm and uniform nuclei. *D* FNA smear of the lesion shown in *B*. This is a highly pleomorphic malignant tumor that is indistinguishable from a metastatic large-cell carcinoma of any origin.

TUMORS OF THE ADRENAL MEDULLA

Pheochromocytoma

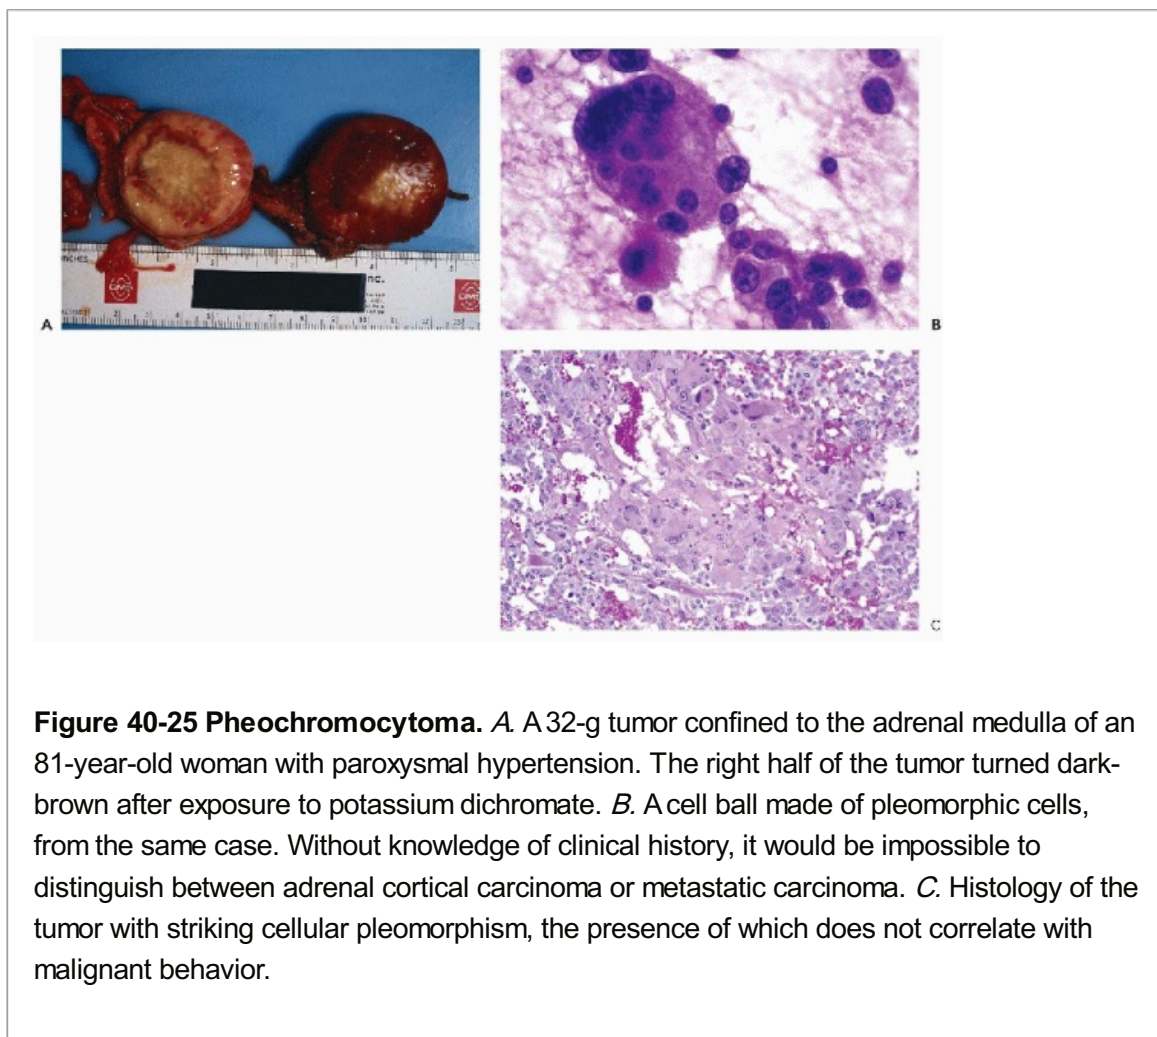

Pheochromocytomas and the related tumors, **paragangliomas**, belong to the group of tumors **derived from the neural crest**. The distribution of these tumors follows the position of the parasympathetic ganglia and includes the **carotid body tumor** and **retroperitoneal tumors originating in the organ of Zuckerkandl**. Pheochromocytomas may also occur in **the wall of the urinary bladder** and in other, still less common locations. All of these tumors are capable of forming **blood-pressure-regulating hormones (the catecholamins)** and related compounds, such as **adrenaline and noradrenaline**. The release of these hormones may cause **permanent or transient hypertension** (also known as **paroxysmal hypertension**) (for a recent review see Ellison and Parkham, 2001). Carotid body tumors are discussed in Chapter 30, and bladder tumors are discussed in Chapter 23.

Adrenal pheochromocytoma is the most common member of this family of tumors. Manasse

(1893) described brown staining of these tumors with salts of chromium, hence the old name of **chromaffinoma**. The term **pheochromocytoma** was introduced by Pick (1912) because the tumor turns dark brown after exposure to potassium dichromate (Fig. 40-25A).

Pheochromocytomas, also known as **intraadrenal paragangliomas**, are relatively common neoplasms that are capable of **producing adrenaline and noradrenaline** (see Table 40-7). These tumors, which can occur in any age group, including children and young adults, are a known cause of **paroxysmal hypertension**. Sudden attacks of headache, perspiration, and palpitation associated with a sudden rise in blood pressure are characteristic of this disorder. The demonstration of **urinary catecholamins and their products**, particularly **vanillylmandelic acid (VMA)**, is diagnostic of the disease. Surgical removal of the tumor cures the hypertension.

P.1489

The **rule of 10** is often used to define the **key clinical characteristics of pheochromocytomas**: 10% are asymptomatic, 10% are familial and usually bilateral, 10% occur in the pediatric age group, 10% occur in organs other than the adrenal, 10% of sporadic tumors are bilateral, and 10% are malignant. The familial tumors are usually associated with **multiple endocrine neoplasias (MEN) type IIA (Sipple's syndrome)** with concurrent medullary carcinomas of the thyroid and hyperplasia of the parathyroid or **type IIB** (with concurrent medullary carcinoma of the thyroid and multiple neuromas), and with **von Hippel-Lindau, von Recklinghausen, and Sturge-Weber syndromes** (Neumann et al, 1993; Eisenhofer et al, 2001). A recent molecular analysis revealed that about 25% of patients with

sporadic tumors are carriers of several **germ line mutations** (Neumann et al, 2002).

Pathology

Pheochromocytomas range from **small**, well-circumscribed lesions that are confined to the adrenal medulla (Fig. 40-25A), to **enormous hemorrhagic masses** weighing several kilograms. In contrast to the cortical adrenal tumors, which are primarily yellow, the pheochromocytomas usually have a **red-brown** cut surface, with larger tumors often showing hemorrhage and cystic degeneration.

Histology

The **classic pattern** of pheochromocytoma is somewhat similar to that of the normal adrenal medulla, and consists of **large polygonal, pleomorphic, and spindly cells arranged in thick nests or Zellballen** (German for cell balls), **separated from each other by a rich capillary vascular network**. The **cytoplasm** is intensely granular, stains pink to purple in H&E stain, and may show PAS-positive eosinophilic globules. The **nuclei** may be highly pleomorphic, and **multinucleation** is common (see Figs. 40-25C and 40-26D). **Dispersed tumor giant cells with very large nuclei** are often seen. On electron microscopy, dense core endocrine granules are found in the cytoplasm. Rare variants of this tumor are **pigmented pheochromocytoma** (Chetty et al, 1993) and pheochromocytoma composed of **granular oncocytic cells** (Li and Wenig, 2000). A case of this tumor **mimicking RCC** has been reported (Unger et al, 1990). **Composite tumors of the adrenal medulla**, containing elements of **pheochromocytoma, neuroblastoma, and ganglioneuroma**, have been described (Tischler, 2000).

Except in the presence of distant metastases, there are **no absolute histologic criteria by which to distinguish benign from malignant pheochromocytoma**. Large tumor size, the presence of vascular invasion, and extensive local invasion are seen more frequently in malignant than in benign tumors (Linnoila et al, 1990).

Recently an attempt was made to establish **a scaled score** separating benign from malignant tumors based on a large number of microscopic criteria (Thompson, 2002). The value of this score remains to be determined by prospective testing. As is the case with other endocrine tumors, **DNA ploidy** of these tumors has not been particularly helpful,

P.1490

although it appears that some aneuploid tumors are more likely to metastasize compared to diploid tumors (Amberson et al, 1987; Nativ et al, 1992; Garcia-Escudero et al, 2001). However, even malignant pheochromocytomas grow slowly and have a 50% 5-year survival rate. The common metastatic sites include the lymph nodes, bone, and liver. Paradoxically, the **highly pleomorphic tumors are more likely to behave in a benign fashion** than the more-orderly tumors.

Figure 40-26 Pheochromocytomas. *A.* Aspirate of a histologically confirmed tumor. The smear contained small clusters of small cells and numerous capillaries, the latter of which are important in the diagnosis. *B,C.* Retroperitoneal pheochromocytoma with large spindly tumor cells mimicking a sarcoma. The 43-year-old female presented with hypertension. *D.* Resected tumor composed of Zellballen surrounded by capillaries.

Pheochromocytomas are easily distinguished from nearly all tumors occurring in this anatomic area. In case of doubt, the **positive chromogranin immunostain** will separate this tumor from ACC, RCC, hepatocellular carcinoma, and metastatic adenocarcinoma.

Cytology

FNA biopsy of suspected pheochromocytomas and related tumors, such as the carotid body tumor, should be avoided for fear of inducing a fatal hypertensive crisis (Engzell et al, 1971; CaSola et al, 1986). A handful of cases of pheochromocytoma in aspirates have been reported by Tsuzaki et al (1978), Zajicek (1979), Nguyen (1982), Gonzales-Campora et al (1988), and Wadih et al (1992). Frable (1976) described a metastatic tumor to the femur. The **classic pattern of Zellballen** is sometimes observed, particularly in **intraoperative scrape smears** (Shidham et al, 1999), but it is usually absent in FNA material. In fact, based on our own limited experience and review of the scanty literature, there is probably no single cytologic pattern that is diagnostic of this lesion. In general, the presence of tumor cells of various types in the company of **numerous capillaries** has been observed by us (Koss et al, 1992).

We have seen FNA specimens from three patients with adrenal pheochromocytoma. The FNA of one of the tumors (7 cm in diameter) revealed a **highly pleomorphic cell population with clear nuclear features of a malignant tumor** (Fig. 40-25B,C). In one other adrenal pheochromocytoma, the smear pattern was similar, but there was **also a population of smaller tumor cells**. Deodhare et al (1996) reported a case of FNA of a pheochromocytoma of the adrenal **mimicking a small-cell carcinoma**.

In yet another case, seen in consultation, a pattern of small tumor cells in small clusters, with a central lumen, was vaguely reminiscent of Zellballen (Fig. 40-26A). The cells were accompanied by **numerous capillaries** that were perhaps more important than the cells in

suggesting the diagnosis. In a case of **retroperitoneal pheochromocytoma**, the cells were **predominantly spindly** and suggestive of a sarcoma, although the histology of the primary tumor was rather conventional (Fig. 40-26B-D). In a case reported

P.1491

by Vera-Alvarez et al (1993), intranuclear cytoplasmic inclusions were observed in tumor cells. Layfield et al (1987) described a **mixed tumor of the adrenal that contained elements of a pheochromocytoma and ganglioneuroma**. Features of both tumor types were present in the FNA smears.

Thus, the **cytologic picture of pheochromocytoma** in FNA specimens is **rarely conclusive**, and the diagnosis must be supported by clinical, imaging, and biochemical data.

Neuroblastomas and Related Tumors

Neuroblastoma

Clinical Data

Neuroblastomas are the **most common extracranial solid tumors of childhood** (Matthey, 1985; Shimada, 1993). Approximately 500 new cases are diagnosed each year in the United States. The tumor usually occurs in patients **younger than 5 years of age**, although rare examples have been reported in adults (MacKay et al, 1976; Allan et al, 1986; Kaye et al, 1986). Most cases of neuroblastoma occur in the **adrenal medulla** and appear as an **abdominal mass**. Some of these tumors may be primary in the **posterior mediastinum and pelvic area**. Histologically identical tumors may also occur in the **nasal cavity of adults**, in which case they are known as **esthesineuroblastoma**.

Unlike Wilms' tumor, which occurs in the same age group, **neuroblastoma often presents with metastatic disease**, particularly to the bones of the skull (where it may cause a **sun-ray** appearance of the vertical bony spicules) but also to other bones. **The most common clinical error made in the diagnosis of neuroblastoma is the diagnosis of acute lymphoblastic leukemia, based on faulty interpretation of bone marrow smears.**

The **prognosis** for a patient with neuroblastoma depends on numerous variables, such as age at diagnosis, clinical stage, tumor grade based on the proportion of Schwannian stroma, the proportion of differentiating cells, and several genetic and molecular features. The most important genetic feature is **amplification of the N-myc oncogene**, vested in double-minute chromosomes. A prognostic classification system proposed by Shimada et al (1995, 1999, 2001) and known as the **Shimada system** is widely used (Ambros et al, 2002). Although FNA biopsy can be **extremely helpful in diagnosing the disease, particularly in clinically obscure situations**, it may not be adequate for fully evaluating the tumor and determining the optimum treatment.

Histology

Neuroblastoma is a **tumor of the primitive nerve cells**, and mimics the events of formation of nervous tissue during embryonal life. It is often considered to be the **prototype of the "small blue cell tumors of childhood"** because its basic component is **small cancer cells with round or slightly molded nuclei with scanty cytoplasm**. However, the **arrangements of these cells in rosettes (Homer-Wright rosettes) and the presence of primitive neurofilaments (neuropil)** are fairly unique and readily recognizable in most cases. The histology of **esthesineuroblastoma** of the nasal cavity is identical to that of neuroblastoma.

The **rosettes** formed by neuroblastomas consist of a multilayer formation of **small tumor cells surrounding a central space** that is filled with disorderly **tangles of thin neurofibrils** (Fig. 40-27A). The presence of neurofibrils can be best documented with one of the silver impregnation stains.

The tumor cells, which are **primitive neurons (neuroblasts)**, may **mature and differentiate into ganglion cells and Schwann cells** (Joshi, 1992; Goto et al, 2001). **The process of maturation, which is limited to scattered tumor cells in neuroblastomas**, may become extensive, leading to **ganglioneuroblastoma**. This is a tumor of **uncertain prognosis** that is composed of **primitive neural cells and ganglion cells in approximately equal proportions, in a background of increasing Schwann cells**. The transformation may lead to **benign ganglioneuroma**, wherein the process of **maturation of primitive cells into ganglion cells and Schwann cells has been completed**, sometimes many years after the discovery of the primary tumor. Neuroblastomas that show focal differentiation into ganglion cells have a better prognosis, particularly in patients who are younger than 18 months of age.

Cytology

Very few clinically suspected **primary neuroblastomas of the adrenal** are subjected to FNA because the full assessment of optimal diagnostic and prognostic information requires a generous incisional biopsy of the tumors (Joshi, 2000). On the other hand, **FNA is most valuable in the staging of neuroblastomas and the diagnosis of this tumor in nonadrenal and metastatic sites**.

Our experience is based mainly on FNA of extra-adrenal sites, such as metastases to bone or liver, in which FNA was helpful in the **diagnosis or the workup for staging**. The smears are usually rich in **small tumor cells with homogenous hyperchromatic nuclei and a tiny rim of cytoplasm**. **The cells are either dispersed or form small clusters**. The clusters must be very carefully examined in the search for **typical Homer-Wright rosettes composed of several rows of cells arranged around an approximately circular space that is either empty or filled with fine neurofilaments**. This finding is diagnostic of neuroblastoma (Fig. 40-27C). **The rosettes are often distorted and composed of disorderly clusters of small cells and small, empty, central spaces**. The **neurofibrils** can also be seen outside the rosettes under high power of the microscope as **tangled, thin, eosinophilic lines** that should not be mistaken for a contaminant. If material is available, the **identification of the neurofibrils** is facilitated by a silver stain or another specific stain (Koss et al, 1992). The diagnosis is also easier to establish if **scattered larger neuroblasts and ganglion cells are observed, as is the case** in differentiating tumors. Neuroendocrine markers are positive in neuroblastoma (Frostad et al, 1998). Frostad et al (1999) used FNA material from 18 children with neuroblastoma to perform a number of studies of **prognostic significance**, including DNA ploidy determination and fluorescent in situ hybridization

P.1492

(FISH), to document **chromosomal abnormalities and amplification of the oncogene N-myc**. The results were remarkably **concordant with the same studies performed on tissue samples**.

Figure 40-27 Neuroblastoma and ganglioneuroma. *A.* Homer-Wright rosettes in an esthesioneuroblastoma (olfactory neuroblastoma) of the sellar region in a 27-year-old man. *B.* Metastatic neuroblastoma in a cervical lymph node aspirate from the above patient. Note the rosette formation by the small tumor cells. *C.* Rosettes in adrenal neuroblastoma in a young boy. *D.* Cytology of adrenal ganglioneuroma. There are two large ganglion cells with abundant pink, granular cytoplasm surrounded by spindle-shaped Schwann cells. (*C,D*: MGG stain.) (Courtesy of Drs. Edneia Tani and Lambert Skoog, Stockholm.).

In a child or a young adult, the **differential diagnosis** of neuroblastoma in smears includes **Ewing's sarcoma, lymphoblastic leukemia, lymphoma, embryonal rhabdomyosarcoma, or a primitive neuroectodermal tumor**. Many of these tumors have a fairly specific immunochemical profile (Frostad et al, 2002). Furthermore, none of these tumors forms **Homer-Wright rosettes or neurofilaments**, although rosette-like structures may occur in Ewing's tumors (see Chap. 36). In the rare cases of **neuroblastoma or esthesioneuroblastoma in adults**, the tumors must be differentiated from small-cell endocrine carcinomas and related lesions, and, very remotely, from a metastatic Merkel cell carcinoma (see Chap. 34).

Ganglioneuroblastoma

Ganglioneuroblastoma, which is usually seen in children, is **intermediate between a neuroblastoma and a fully differentiated ganglioneuroma**. It shows a **mixture of immature neural cells** (characteristic of neuroblastoma), **mature ganglion cells**, and **bundles of Schwann cells and delicate neurofilaments**. The prognosis depends on the proportion of immature neuroblasts and ganglion cells. For patients with tumors dominated by ganglion cells and Schwann cells, the survival rate is excellent (Umehara et al, 2000).

The **cytology** of these tumors shows features of neuroblastoma (described above) and ganglioneuroma (described below) (Taylor and Nunez, 1984; Koss et al, 1992).

Ganglioneuroma

Ganglioneuroma is an uncommon, fully **differentiated counterpart of neuroblastoma that consists of bundles of Schwann cells, ganglion cells, and neurofilaments**. This **benign**

tumor usually occurs in the posterior compartment of the **mediastinum or in the retroperitoneal space**. About one third of ganglioneuromas are found in the **adrenal**. Resection is curative of the tumor.

Cytology

Taylor and Nunez (1984) described the FNA smear of a ganglioneuroma of the adrenal, and another case was described by Koss et al (1992). The finding of **numerous large, mature ganglion cells** is key to the diagnosis (Fig. 40-27D).

P.1493

If **small neuroblasts are present**, the diagnosis of a **ganglioneuroblastoma** cannot be excluded.

METASTATIC TUMORS

The adrenal glands are the fourth most common site of blood borne metastatic cancer, next to the lung, liver, and bone (Willis, 1973). **Metastases are far more common than primary malignant tumors of the adrenal gland** (Glomset, 1938). Almost 30% of patients with metastasizing tumors of diverse primary sites of origin are reported to have adrenal metastases, half of which are in both glands (Abrams et al, 1950). In a large series from a cancer center reviewed by Saboorian et al (1995), the number of metastatic cancers was equal to the number of primary cortical lesions, most of which were benign adenomas.

In Abrams et al's (1950) **large series**, primary tumors of the **lung** (Fig. 40-28A) and **breast** accounted for a majority of adrenal metastases, followed by tumors of the **gastrointestinal tract, kidney, and ovary**. Lung tumors, followed by **RCCs** and **malignant melanomas**, were the tumors most often seen by Saboorian et al (1995). In our experience, lung and breast tumors accounted for 60% of the metastases; however, other tumors can also metastasize to the adrenals.

Figure 40-28 Metastatic tumors of the adrenal gland. A. Metastatic adenocarcinoma of lung. B. Metastatic eye melanoma to adrenal in an 80-year-old female. The melanin pigment is green in Diff-Quik stain. C. Same tumor as in B, with Pap stain. Note the large intranuclear cytoplasmic inclusions in cancer cells. D. Cell block of the same tumor

showing pigment formation.

When the primary cancer site is known, cytologic recognition of the metastatic tumor is usually easy to achieve, and is greatly aided by comparison with slides of the primary tumor. In cases with an unknown primary site, **mucicarmine stain** is useful for diagnosing metastatic **adenocarcinoma**. The characteristic features of metastatic mammary carcinomas are discussed in the appropriate chapters. We have noted that along with pigmented tumor cells, the presence of **large cancer cells with intranuclear cytoplasmic inclusions ("nuclear holes")** is often observed in **metastatic melanomas** (Fig. 40-28B-D).

Perhaps the most challenging task is to distinguish the occasional case of **hormonally inactive ACC** from **metastatic renal carcinoma (RCC)**. Immunohistochemistry may be helpful. Although both tumors are usually **vimentin-positive**, whereas other metastatic carcinomas are **vimentin-negative**, **EMA and cytokeratins** are usually **positive in RCC** and **negative or focally positive in adrenal cortical neoplasms**.

RESULTS AND CONCLUSIONS

FNA biopsy of an adrenal mass is **simple, safe, and cost-effective** in establishing the identity of space-occupying lesions

P.1494

of the adrenal tumors found by either clinical examination or scanning of the abdomen. The method is also helpful in the staging of tumors (Koss et al, 1992; Saboorian et al, 1995). Approximately one half of the aspirates represent metastatic cancer to the adrenal gland (Wadih et al, 1992). As stated above, a vast majority of the primary adrenal tumors are benign, and with reasonable experience can be diagnosed by FNA. In asymptomatic patients, smaller lesions can be left alone, whereas masses greater than 6 cm must be surgically removed (Barzon and Boscaro, 2000). However, small carcinomas do occur. We recently observed an adrenal cortical carcinoma measuring only 3 cm in diameter (see Fig. 40-24A). This is a strong argument for employing FNA in the workup for smaller adrenal nodules (Saboorian et al, 1995).

The **sensitivity** of adrenal FNA for detecting cancer is approximately 85%, and the **specificity** approaches 100% (Zornoza, 1981; Katz et al, 1984; Bernardino et al, 1985; Montali et al, 1992). **False-negative** diagnoses are usually caused by an **inadequate sampling procedure**, whereas **false-positive** diagnoses are usually caused by **the misinterpretation of scanty adrenal cortical cells as the clear cell variant of RCC or a hepatocellular carcinoma** (Karstrop, 1991). In a study of 24 children with neuroblastic tumors, Frostad et al (1998) reported an accuracy of 97%. It remains difficult to distinguish an adenoma from a well-differentiated ACC in both cytologic and histologic specimens. It has been our experience that intensely pink and granular cytoplasm is rarely seen in adrenal adenoma, and numerous lipid droplets are not seen in carcinoma. Clinical information is absolutely essential for the accurate assessment of adrenal FNA biopsies. FNA may assist in the selection of the appropriate mode of therapy.

THE RETROPERITONEUM

The **retroperitoneal space** is located in the posterior abdomen, and is demarcated anteriorly by the posterior layer of the peritoneum and posteriorly by the skeletal muscles and fasciae of the posterior abdominal wall. It extends from the diaphragm down to the floor of the pelvis. In addition to the major retroperitoneal abdominal organs (i.e., the pancreas, kidneys, adrenals,

and duodenum), the retroperitoneal space contains the **abdominal aorta, inferior vena cava, sympathetic nerve trunks, and celiac and sacral nerve ganglion plexuses**. The retroperitoneal space is filled with **loose connective tissue and fat-harboring lymphatic vessels, chains of lymph nodes, and nerves**. All of these structures may give rise to primary tumors.

The retroperitoneal space is the site of numerous pathologic processes, most of which are malignant (Katz, 1997a). Excluding tumors that arise in major retroperitoneal organs (i.e., the pancreas, kidneys and adrenals, as described in the preceding pages and other chapters in this book), tumors of the retroperitoneum are not unique to this site. The most common malignant retroperitoneal tumors are **metastases from cancers of the genitourinary tract**, followed by **malignant lymphomas** that can be either primary or metastatic. The less common primary retroperitoneal tumors include a variety of **soft part sarcomas**, tumors derived from neural crest, and, very rarely, primary germ cell tumors. The retroperitoneum may also be the site of various benign space-occupying lesions.

The clinical, histologic, and cytologic features of most of the neoplastic lesions are discussed at length in various chapters of this book, and therefore are only briefly described and illustrated here. The primary purpose of this contribution is to present a cohesive summary of the various lesions, and their relative frequency and differential diagnosis, and to stress the need for ancillary studies that must be clinically relevant and cost-effective.

INDICATIONS AND TECHNIQUES

Space-occupying lesions located in the retroperitoneal space constitute a **prime target for FNA**. Surgical exploration of this large area of the body for diagnostic purposes is technically not easy, and is not without considerable risk to the patient.

The basic concept of transcutaneous retroperitoneal FNA originated with Göthlin (1976), who injected radiopaque material into the dorsum of the foot to opacify retroperitoneal lymph nodes that could be aspirated under fluoroscopic control. This procedure, known as **lymphangiography**, was not without problems in terms of sampling and interpretation because the exposure of lymph nodes to radiopaque material resulted in a granulomatous foreign-body reaction and fibrosis that obscured the presence of tumor cells (Glatstein et al, 1969; Wallace et al, 1977; Lee et al, 1980). The first application of these techniques was for **staging of Hodgkin's disease** (Brascho et al, 1977), in which radiologic examination of the opacified lymph nodes replaced staging laparotomy (Goffinet et al, 1973).

The imaging of the retroperitoneal space and its transcutaneous aspiration is now guided by **CT** and **US**, the latter being particularly useful for identifying cystic lesions (Stephens et al, 1977; Bree et al, 1984; Knelson et al, 1989). Currently, any **space-occupying lesions** of the retroperitoneum may be aspirated (Koss et al, 1992).

MRI can now be used to visualize retroperitoneal lesions and lymph nodes; however, it cannot be used as a guide for aspiration biopsy with metallic needles (Nishimura et al, 2001; Grubnic et al, 2002).

The initial applications of retroperitoneal FNA were for **staging of malignant lymphomas and tumors of the genitourinary tract** by sampling **pelvic and retroperitoneal lymph nodes** (Zornoza et al, 1977a,b; Bonfiglio et al, 1979; Dunnick et al, 1980; Eframides et al, 1981; Zornoza et al, 1981a; Eideken-Monroe et al, 1982; Cochand-Priollet et al, 1987; Kohler et al, 1990). Cancers of the **cervix, endometrium, and ovary** in women, and the **testis** and

prostate in men were the targets of these investigations.

The **approach used** by interventional radiologists to aspirate

P.1495

retroperitoneal lesions varies depending on the size and location of the lesion. The guiding principle is to reach the lesion by the shortest possible route, with the least possible injury to the patient. **Thus, anterior, lateral and posterior approaches** may be selected and the patient is positioned appropriately. In some cases, even a transhepatic approach may be chosen. It is of interest that when the anterior approach is used, the needle crosses intestinal loops and sometimes major vessels without significant complications. A case of **needle tract seeding of a liposarcoma** was described by Hidai et al (1983).

TABLE 40-8 SPACE-OCCUPYING LESIONS OF THE RETROPERITONEUM

Inflammatory lesions

- Abscesses
- Other inflammatory lesions

Benign cystic lesions

Miscellaneous benign lesions

Lesions of lymph nodes

- Reactive lymphoid hyperplasia
- Malignant lymphomas
- Hodgkin's disease
- Non-Hodgkin's lymphoma

Mesenchymal tumors

Adipose tissue: lipoma, liposarcoma, lipomyxosarcoma

Smooth muscle: leiomyoma, leiomyosarcoma

Fibrous connective tissue: idiopathic retroperitoneal fibrosis, fibroma, fibrosarcoma

Blood vessels: hemangioma, hemangiopericytoma, angiosarcoma

Tumors of neural crest

Neurilemmoma, malignant schwannoma

Neurogenic sarcoma

Neuroblastoma

Ganglioneuroblastoma

Ganglioneuroma

Paraganglioma (pheochromocytoma)

Chordoma**Miscellaneous primary tumors****Metastatic tumors****Targets of Aspiration Biopsy in the Retroperitoneal Space**

Table 40-8 lists space-occupying lesions of the retroperitoneum that may be the target of aspiration biopsies. Lesions of the pancreas, kidney, and adrenals are discussed elsewhere in this chapter and in Chapter 39.

NORMAL CELLULAR COMPONENTS

The only normal benign cells of retroperitoneal origin are occasional **fibroblasts**, **capillary endothelium**, and **fat cells**. However, it is not uncommon **to observe in aspirates of the retroperitoneum benign cells of intraabdominal organs** that are inadvertently sampled during the aspiration procedure. Most commonly observed are **mesothelial cells**, followed by **pancreatic ductal cells**, **gastric epithelium**, **colonic epithelium**, and **hepatocytes**. These benign cellular components are extensively illustrated in other chapters. Although vesicles are not retroperitoneal in location, the seminal vesicles may be aspirated (see Chap. 33).

BENIGN LESIONS**Inflammatory Lesions*****Abscesses***

Retroperitoneal abscesses are uncommon and are usually secondary to pelvic abscesses caused by a bacterial infection (Koehler and Moss, 1980). Although we have not personally observed a case, it may be assumed that the aspirate will consist of purulent material.

Tuberculosis and Related Infections

Tuberculosis involving the **retroperitoneal lymph nodes** is common in parts of the world

where the disease is still prevalent, and is occasionally seen in the United States in immigrant populations. **Pott's disease or tuberculous spondylitis**, involving the vertebral column and the adjacent muscles and fasciae, may also present as a retroperitoneal mass. In **patients with AIDS, *Mycobacterium avium intracellulare* infection** is common. For a description of the cytologic manifestations of these disorders, see Chapter 31.

Parasitic Diseases

Paragonimus westermanii, a lung fluke, can spread to the retroperitoneal space and cause cystic, tumor-like swelling (Jeong et al, 1999). The diagnosis can be established by finding the characteristic ova, as described in Chapter 19.

Hydatid cysts, caused by ***Ecchinococcus granulosus*** infestation, may occur in the retroperitoneal space (Sener et al, 2001). For a description of the cytologic findings, see Chapters 19 and 38.

Filariae may also cause retroperitoneal masses. A case of FNA-diagnosed lesions caused by ***Dirofilaria repens*** was described by Roussel et al (1990).

Cysts and Other Benign Lesions

Cysts in the retroperitoneum are rare and may be of **enteric, lymphatic, or dermoid type**. The **enteric and lymphatic cysts** are surfaced by a simple single layer of **flattened epithelium**, surrounded by a fibrous tissue capsule. They may occur in children (Okur et al, 1997). The **exquisitely rare primary dermoid cysts** mimic similar tumors of the ovary (see Chap. 15).

Bronchogenic cysts, lined by ciliated epithelium, may occur in the retroperitoneal space (Haddadin et al, 2001; Ingu et al, 2002). A histologically similar cyst of the mesentery and retroperitoneum was diagnosed as a Müllerian cyst by Lee et al (1998).

P.1496

Cystic lesions may also occur as a consequence of a **retroperitoneal hematoma** (Ushida et al, 2000) or by cystic degeneration of solid tumors.

Cytology

The rarity of the retroperitoneal cysts precludes a large cytologic experience with these lesions. In our limited experience, the aspirate may yield fluids of various amounts, colors, and consistencies depending on the nature of the cyst. The sediment is usually very scanty. It may contain **epithelial cells**, singly and in small clusters, and **macrophages**. In bronchial cysts, the epithelium is **ciliated** and similar to normal bronchial cells (see Chap. 19).

Idiopathic Retroperitoneal Fibrosis

Idiopathic retroperitoneal fibrosis is a rare, **progressive tumor-like lesion** that usually occurs in adults and **simulates a soft-tissue sarcoma** on imaging studies. The etiology is unknown. Progressive fibrosis narrows and characteristically displaces the ureters medially, and may lead to ureteral obstruction and renal failure. Resection is not possible, and **sections of biopsy specimens** reveal benign, proliferating fibroblasts, either with or without collagen and hyaline stroma, accompanied by an inflammatory infiltrate, usually composed of lymphocytes (Fig. 40-29A).

Figure 40-29 *A*. Retroperitoneal fibrosis in a 56-year-old woman. Note the proliferating fibroblasts in a dense collagenized stroma with a few lymphocytes. *B*. Needle core biopsy of abdominal fibromatosis. The corresponding FNA smears were not diagnostic. *C, D*. Low- and high-power view of a retroperitoneal schwannoma. Note the dark bands formed by palisading cells (Verocay bodies).

Cytology

Stein et al (1997) described the findings in three cases of idiopathic retroperitoneal fibrosis. Reactive **fibroblasts**, with conspicuous nucleoli, **sheets of fibrous tissue and inflammatory cells**, predominantly lymphocytes, were present in all cases. The authors suggested that the diagnosis could be established on FNA if supported by clinical and imaging data. In our experience, a cytologic diagnosis is difficult to establish because of the paucity of cells. Needle core biopsy is more rewarding (Fig. 40-29B).

Miscellaneous Rare Lesions

Endometriosis may be the cause of retroperitoneal masses (Rana et al, 2001). To our knowledge, there is no recorded case of cytologic diagnosis of endometriosis in this location (see Chap. 14).

Myelolipoma has been observed in the adrenal gland (see above), but it may also occur in extra- and para-adrenal locations (Spanta et al, 1999).

Malakoplakia has been observed as a **retroperitoneal pelvic mass** diagnosed by FNA (Perez-Barrios et al, 1992). For a description of the cytologic findings in malakoplakia, see Chapter 22.

Benign mesenchymal tumors (listed in Table 40-8) are extremely rare in the retroperitoneal space. Their cytology is described in Chapter 35.

P.1497

RETROPERITONEAL LYMPHADENOPATHY

Lymph node enlargement is one of the most common targets of retroperitoneal FNA. It

may be caused by a **benign reactive hyperplasia**, a **malignant lymphoma**, or a **metastatic tumor**. In many cases, the clinician or radiologist cannot express a preference for one of these three diagnostic options, and the FNA may be the first approach for elucidating the nature of the illness.

Benign Reactive Hyperplasia

In benign reactive hyperplasia, **the enlarged lymph nodes are usually discrete** and rarely matted together. The causes are various, with a reaction to an **infectious process** being the most common. However, as discussed at length in Chapter 31, there are **many other causes** of reactive lymph node enlargement that may also involve the retroperitoneal lymph nodes.

In our experience, benign hyperplastic retroperitoneal lymph nodes are **rarely aspirated**. Except for **granulomatous lymphadenitis**, the cytologic recognition of this disorder is difficult to achieve, perhaps because the diagnosis is not anticipated (Koss et al, 1992).

Figure 40-30 *A*. Reactive lymph node. The polymorphic cell population of mature and immature lymphocytes along with a tingible body macrophage is diagnostic. *B*. Tissue from a hyperplastic lymph node. *C, D*. Malignant lymphoma mimicking small-cell carcinoma. *C*. The air-dried and Diff-Quik-stained smear of this retroperitoneal lymph node FNA shows conspicuous molding but no single cell necrosis. *D*. Leukocyte common antigen (CD-45) positivity confirms the diagnosis of malignant lymphoma.

As described in Chapter 31, the smears of hyperplastic lymph nodes are usually rich in **lymphocytes in various stages of maturation**, and contain **tingible body macrophages** (Fig. 40-30A,B). The lingering possibility in these situations is that the sampling was inadequate, and a malignant lymphoma or metastatic tumor may not have been recognized. There is usually not enough material with which to perform immunologic studies and, therefore, the **diagnosis should be rendered with caution**. Unless the clinical and imaging data strongly support the benign verdict, quite often an exploratory laparotomy is also performed to secure a tissue sample for confirmation.

Malignant Lymphomas

Approximately one quarter of all retroperitoneal masses are secondary to involvement by lymphoma (Katz, 1997a). In most cases the retroperitoneal abnormalities occur **in patients with known lymphomas**, and the FNA procedure is used mainly to confirm the **diagnosis and staging**. **Primary retroperitoneal lymphoma** is relatively uncommon.

P.1498

As discussed in Chapter 31, the diagnosis of **Hodgkin's disease** and the **diagnosis and typing of non-Hodgkin's lymphoma** based on conventionally stained FNA-aspirated material from lymph nodes **have their limitations** (Cafferty et al, 1990; Katz, 1997b,c; Weiss and Pitts, 2001). The problems are less severe in staging of lymphomas of known type, although difficulties may be experienced in recognizing **recurrent lymphoma after treatment by radiotherapy or chemotherapy** (Koss et al, 1992).

Problems with the **primary diagnosis of retroperitoneal lymphomas** are often caused by scarcity of the diagnostic material, and uncertain clinical and imaging data. Ancillary procedures such as **immunocytochemistry, image analysis, and flow cytometry** are essential in most cases, as discussed in Chapter 31. The primary diagnosis of malignant lymphoma is further complicated by the fact that a number of **other primary or metastatic retroperitoneal tumors, composed of small cells**, may mimic a malignant lymphoma or vice versa (Fig. 40-30B,C). **Neuroblastoma** or other malignant tumors composed of **small blue cells** in children, and **metastatic germ cell testicular or ovarian tumors** in **adults** may be mistaken for a lymphoma. The morphologic, immunologic, and molecular features of these tumors are discussed in the appropriate chapters. Further, it has been our experience that the **source of metastases** in the testis or the ovary may be inapparent or occult, and the search for the primary tumor is triggered by the retroperitoneal aspiration. For further comments on metastatic tumors to the retroperitoneum, see below.

OTHER PRIMARY MALIGNANT TUMORS

Tumors of Mesenchymal Origin

Table 40-8 lists the benign and malignant tumors of mesenchymal origin. The retroperitoneum is the **primary site of approximately 13% of all sarcomas** (Jaques et al, 1989), which constitute only **8% of all retroperitoneal masses observed in FNA** (Katz, 1997a). These sarcomas are described in detail in Chapter 35. The success and failure of aspiration biopsy of mesenchymal tumors depends on the quality and cellularity of the sample. Regardless of the skill of the operator, some lesions of connective tissue origin will yield small samples of cells that are inadequate for diagnosis (see comments above on retroperitoneal fibrosis). Even with optimal samples, though, it may be difficult to differentiate between benign and malignant lesions.

Prime **examples** of such problems are the differentiation of a **lipoma from a well-differentiated liposarcoma** (Tallini et al, 1993), a **leiomyoma from a well-differentiated leiomyosarcoma**, or a **benign from a malignant schwannoma** (Koss et al, 1992).

Although **sarcomas are usually, but not always, recognized as malignant tumors**, it may be extremely difficult to classify them precisely from FNA samples (Koss et al, 1992; Ferretti et al, 1997). In many such cases, **an elaborate set of immunocytochemical procedures, electron microscopy, or a genetic study** may be required for accurate classification. As an example, bizarre cancer cells from a case of **retroperitoneal rhabdomyosarcoma** are shown

in Figure 40-31. **It may also be difficult to grade sarcomas** because the FNA sample may not be representative of the tumor. It has been proposed that the latter difficulty can be overcome, to some extent, by **DNA ploidy analysis** of Feulgen-stained smears. In general, **low-grade sarcomas are diploid with a low proliferation index**, whereas **high-grade sarcomas are aneuploid** or tetraploid with an elevated proliferation index (Katz, 1997a). However, there are **many exceptions to this rule** (Agarwal et al, 1991).

Cytology

There is now a modest, but increasing, experience with classifying aspirated primary retroperitoneal mesenchymal tumors (Table 40-9) (Willems, 1983; Koss et al, 1992; Powers et al, 1994; Ferretti et al, 1997). Broadly speaking, the **dominant cytologic patterns** of primary mesenchymal retroperitoneal tumors can be divided into several groups, as discussed at length in Chapter 35 and summarized below:

- Tumors of fatty tissue with mature or immature fat cells (lipomas and liposarcomas)
- Spindle cell tumors [tumors of connective tissue, smooth muscle, nerve, and vessels (angiosarcomas)]
- Sarcomas composed of large cancer cells [epithelial leiomyosarcomas, gastrointestinal stromal (GIST) tumors, rhabdomyosarcomas, large-cell lymphomas, etc.; for example see Fig. 40-31]
- Sarcomas composed of small cancer cells (embryonal rhabdomyosarcomas, neuroblastomas, Ewing sarcomas, and small-cell lymphomas)
- Tumors with special features (chordomas, ganglioneuroblastomas, and ganglioneuromas; see below)

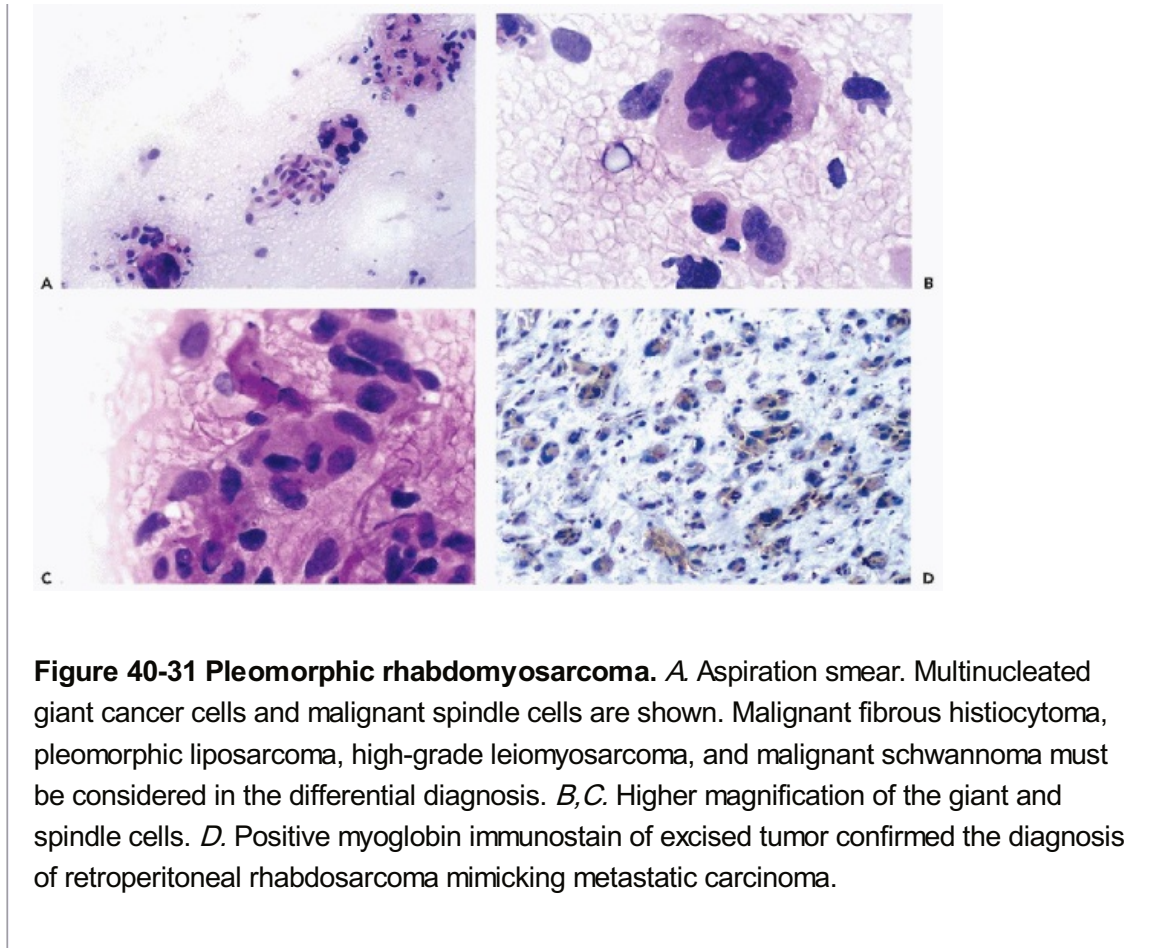

This summary is not all-inclusive, and is based on personal experience that is limited to one or two examples in each category. The differential diagnosis of such cytologic samples **must always include metastatic tumors** of various origins, as discussed below, and usually requires **extensive immunocytochemical analysis**. Unfortunately, the material secured by FNA is usually insufficient for such testing, unless cell blocks are also available. In the absence of conclusive data, it is best to limit the diagnostic conclusion to a general description of the cell pattern (e.g., "spindle cell tumor") and, if possible, a determination as to whether the tumor is benign or malignant. In many such cases, tissue samples may be necessary for a definitive diagnosis.

Tumors of Neural Crest Origin

Neuroblastomas, ganglioneuroblastomas, ganglioneuromas, and pheochromocytomas are described in detail above in the section on the adrenal gland. All of these tumors, **particularly benign and malignant paraganglioma** (extra-adrenal pheochromocytoma), may be **primary in the retroperitoneal space** (Wilson and Ibanez, 1978; Koss et al, 1992; Vera-Alvares et al, 1993; Gupta et al, 1998a; Yen and Cobb, 1998; Jain et al, 1999). Vera-Alvarez et al (1993)

P.1499

observed **intranuclear cytoplasmic inclusions** in a case of malignant paraganglioma.

Miscellaneous Primary Tumors

Cytologic observations have been reported for a number of unusual primary tumors in the retroperitoneal space. Doria et al (1990) described a case of **mesenchymal chondrosarcoma**. This tumor is described in Chapter 36. Motoyama et al (1994) described two cases of **mucinous cystic tumors** of the retroperitoneum, which in all aspects were identical to ovarian tumors of this type (see Chap. 16).

Chordoma

Chordoma, or tumors of the **notochord**, usually occur at the two extremities of the spinal column—at the **cranial end or near the sacrum** (see Chaps. 27 and 36). Sacral tumors may spread to the retroperitoneal space and be aspirated as such. The characteristic **physaliphorous cells**, which mimic cartilage cells and are provided with a large, vacuolated, “bubbly” cytoplasm and a peripheral, spherical nucleus, are diagnostic of this tumor (Fig. 40-32). However, similar cells may be derived from an inadvertently aspirated **nucleus pulposus**, the central portion of a herniated intervertebral cartilage (see Chaps. 27 and 36 and Fig. 36-18).

Primary Germ Cell Tumors

Although germ cell tumors may be primary in the retroperitoneal space (Parkinson and Chabrel, 1984), in all such cases a search for an **occult tumor in the ovary or testis** must be conducted (Bohle et al, 1986). The cytologic presentation of these tumors in aspiration biopsies is discussed in Chapters 15 and 33.

The most common of these tumors are **mature retroperitoneal teratomas, which are**

observed predominantly in infants and children (Arnheim, 1951). They are nearly always benign and mimic identical ovarian tumors (see Chap. 16). A rare case of **malignant transformation of a retroperitoneal teratoma** in a child was described by Ohno and Kanematsu (1998). The cytologic features of the rare **primary seminoma** of the retroperitoneum are identical to the much more common metastatic tumor (discussed below). Husain and Nguyen (1995) described the FNA cytology of a case of a primary retroperitoneal **extragonadal germ cell tumor** with features of embryonal carcinoma of the testis.

METASTATIC TUMORS

Retroperitoneal metastases from overt or sometimes occult **testicular germ cell tumors** are quite common and usually occur in young males, although we have also observed them in men in the fifth decade of life. They very rarely occur with ovarian tumors. With chemotherapy, radiotherapy, and surgery, germ cell tumors of the testes are among the most curable cancers, even when they metastasize to distant sites (for a recent summary see Preiner and Jewett, 1999). The estimated annual incidence of testicular tumors is 7,500, with a cure rate estimated at 95% (Jemal et al, 2002). Estimates for ovarian germ cell tumors are not available.

Retroperitoneal lymph nodes are the usual site of metastases. The **diagnosis** of germ cell tumors is based on **cytomorphology**, but clinical suspicion is often raised by **elevated levels of serum tumor markers**, such as **placental alkaline phosphatase (PLAP)**, **α -fetoprotein (AFP)**, and **β -human chorionic gonadotropin (β -HCG)**.

The most common malignant germ cell tumor in males is a **seminoma** (Fig. 40-33A-D). The identical counterpart in females is the **ovarian dysgerminoma**; however, this tumor very rarely forms retroperitoneal metastases. The **cytology** of primary (Tao et al, 1984) and metastatic seminoma, and the **role of immunostaining in the differential diagnosis** with malignant lymphoma are discussed in Chapters 31 and 33. These tumors shed dispersed large cancer cells with prominent nucleoli. An important diagnostic feature, shown in Figure 40-33C, is the presence of a **tigroid background**, which is observed in air-dried preparations stained with hematologic stains. To rule out the possibility of a metastatic carcinoma or large-cell lymphoma, which may sometimes mimic seminoma cells, immunostains may be helpful. Thus, a **positive cytokeratin stain** would be in favor of a poorly differentiated metastatic carcinoma, CD-45 stain is positive in most lymphomas, and PLAP is positive in seminoma.

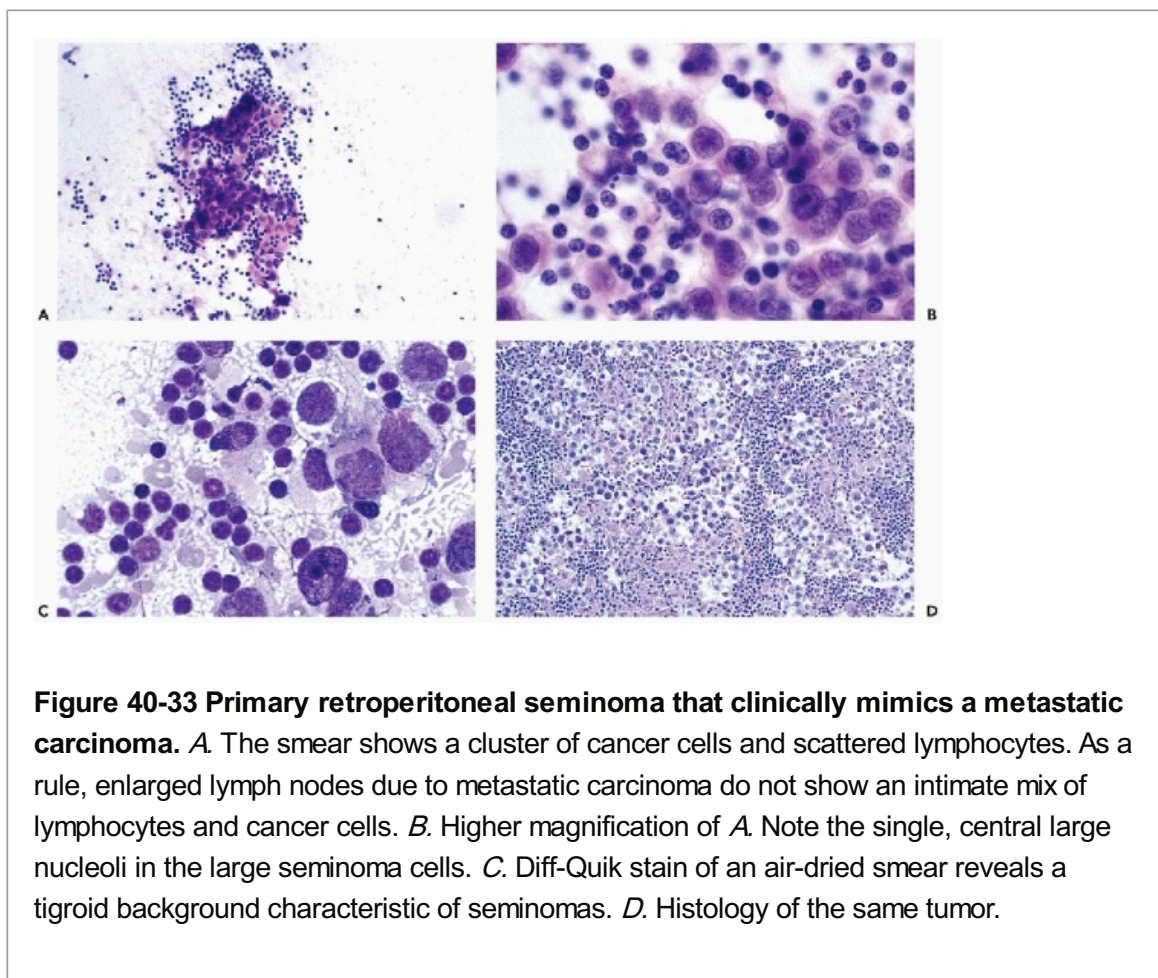

Metastatic embryonal carcinomas and endodermal sinus tumors (or yolk sac tumors) are considered together in aspiration cytology. **In contrast to the dispersed cells seen in**

seminomas, the tumor cells form cohesive clusters consistent with a poorly differentiating adenocarcinoma. In the **endodermal sinus tumor**, PAS-positive, diastase-resistant **hyaline globules** may be observed in the cytoplasm of tumor cells (see Chap. 15). When immunostain for **alphafeto protein** is positive, it is virtually diagnostic of **embryonal carcinoma**.

Metastatic **choriocarcinoma** of **uterine or gonadal origin** is exceptional. Although it is extremely rare for a **gestational choriocarcinoma** to be clinically latent, such cases may occur. As described in Chapter 17, this is a **highly pleomorphic malignant tumor** with two cell types: small **cytotrophoblasts** and large, bizarre, multinucleated **syncytiotrophoblasts**. The smear background is usually necrotic and hemorrhagic. Immunostaining for **β -HCG** is positive in the syncytiotrophoblast.

As discussed in Chapter 33, many testicular germ cell tumors are mixed and may contain, in various proportions, elements of **teratoma, embryonal carcinoma, seminoma, yolk sac tumor, and, rarely, choriocarcinoma**. These mixed patterns may be observed in retroperitoneal metastases. Therefore, FNA smears may show a variety of cytologic patterns side by side.

P.1501

Figure 40-34 Metastatic cancers. *A.* Metastatic endometrial carcinoma in a retroperitoneal lymph node. Note the orderly arrangement of cancer cells in the gland-like structures. The absence of necrosis in the background is against the diagnosis of colonic carcinoma. *B.* Metastatic melanoma. Note the dispersed cancer cells with prominent nucleoli. In this example, a precise diagnosis of tumor type cannot be made.

P.1502

Growing teratoma syndrome is a rare disorder in which metastatic teratomatous masses occur following treatment of nonseminomatous testicular cancers (Ravi, 1995). Although most of these metastases occur in the retroperitoneum, they may also occur in other sites. Good response of these masses to surgical removal has been recorded (Ravi, 1995; Maroto et al, 1997). There is no described cytologic experience with these rare tumors.

Metastatic Carcinomas

Metastatic carcinomas to the retroperitoneal lymph nodes are the most common finding in FNA of retroperitoneal masses (Katz, 1997b, 1997c). The sources are most often **tumors of the pelvic organs**, such as the **prostate, testes, urinary bladder, cervix, vagina, and endometrium** (Fig. 40-34A). Less likely primary sites are the **ovary, kidney, adrenal, stomach, colon, pancreas, lung, breast, and melanoma** (Fig. 40-34B). FNA plays a vital role in staging and may obviate the need for exploratory laparotomy. The cytologic presentation of these tumors is discussed in the appropriate chapters. Briefly, the aspirates are cellular and usually contain **clusters of malignant cells of various types, depending on the primary source**, and are sometimes accompanied by scattered lymphocytes.

RESULTS AND CONCLUSIONS

The diagnosis of metastatic disease in the retroperitoneal lymph nodes by FNA is highly rewarding, with an **accuracy of about 90% and false-negative results in less than 10% of cases**. The latter are usually caused by inadequate sampling relating to the small size or difficult location of the node, or inexperience of the operator. Very few false-positive diagnoses at this site are reported (Bonfiglio et al, 1979; Kidd, 1979; Mennemeyer et al, 1979; Wajsman et al, 1982; Cochand-Priollet et al, 1987; Nagano et al, 1991; Al-Mofleh, 1992). Suen (1994) described and illustrated a false-positive case involving a 49-year-old woman with colonic adenocarcinoma that had been resected 8 months before FNA was performed. In this case, **mesothelial cells** were misinterpreted as adenocarcinoma cells. It has also been our experience that the most common source of diagnostic errors by inexperienced or tired personnel is the **misinterpretation of mesothelial cells as malignant cells**. Most of these

mistakes usually occur at the end of the long day and are based on evidence that is limited to a few clusters of mesothelial cells overstained with one of the hematologic stains. One should also watch out for the extremely rare, inadvertently aspirated **seminal vesicle cells** that may mimic poorly differentiated adenocarcinoma (see Chap. 33). It is prudent to postpone the interpretation of difficult cytologic cases until the next morning when the eyes are fresh and the mind is clear.

41

The Eyelids, Orbit, and Eye

Cytologic diagnosis of various disorders of the eyelids and the external eye has been in use for many years (Kimura and Thygeson, 1955). Naib (1972, 1981) was a major contributor to this knowledge. Cytologic sampling of the orbit, its adnexa, and the eye became possible with the developments of imaging modalities, such as the computed tomography (CT) and precision ultrasound. With the use of small caliber needles under imaging guidance, the aspiration of these organs became safe and accurate (Jakobiec and Chattock, 1978; Czerniak et al, 1983, 1985; Koss et al, 1992; Glasgow and Foos, 1993). In this chapter, the application of cytologic techniques to the external eye, the orbit and its contents will be discussed.

ANATOMIC AND HISTOLOGIC RECALL

The **eye** is located within the bony structure of the skull, the **orbit**. The eye is connected to the brain by the **optic nerve** and to the orbit by a number of **striated muscles** that control its movements. Besides the eye and the muscles, the orbit is filled with loose connective tissue that contains nerves, vessels, and small deposits of lymphocytes.

The anterior surface of the eye, a transparent to light lens-like structure, the **cornea**, is lined on its surface by a transparent, **stratified, nonkeratinized squamous epithelium** (Fig. 41-1A). Laterally, the cornea becomes the **sclera**, a fibrous structure that encloses the eye. The eye is protected anteriorly by the **eyelids** which, on the surface facing the eye, are lined by a stratified epithelium containing numerous **mucus-producing goblet cells**. This epithelium is in continuity with the squamous epithelium lining the cornea; the transition occurs at the **limbus**, where the peripheral cornea merges with the anterior sclera. The outer surface of the eyelids is formed by skin. The eyelids contain numerous **mucus-producing glands**, the largest and most important being the **meibomian glands**. Smaller glands are known as glands of Zeis and Moll. Extending from the eyelids into the orbit are the **lacrimal glands**, similar in structure to **serous salivary glands**, which, by a series of canals, secrete **tears** that lubricate the eye and the eyelids.

The **internal structure of the eye** is extremely complex and beyond the scope of this chapter, thus only the key structures will be mentioned. The interior of the eye is divided into two chambers: the **anterior aqueous chamber**, located between the cornea and the transparent crystalline lens, and the **posterior chamber**, filled with transparent viscous vitreous (vitreous body), demarcated anteriorly by the lens and posteriorly by the retina. The anterior chamber contains a contractile pigmented structure, the **iris**, forming the pupil of the eye and regulating the input of light. All parts of the eye serve the primary purpose of processing light signals by multilayered sensory complex neuronal tissue, the **retina**. The retina can become the site of a malignant tumor of childhood, the **retinoblastoma**. On the outer, orbital side, the retina is supported by a layer of **melanin-containing pigment epithelium** that extends anteriorly into

the iris. In turn, the pigmented epithelium is separated from the sclera by an intermediate layer, the **uvea**, composed

P.1509

of connective tissue containing blood vessels, nerves, and melanocytes. The uvea is divided into three distinct anatomic segments: the **choroid**, which surrounds most of the eye and transits anteriorly into the **ciliary body**, and the **iris**. The most common malignant tumors of the eye, **malignant melanomas**, develop in the uvea, particularly in the **choroid** but also, less commonly, in the **ciliary body** and the **iris**. The **optic nerve** may be the site of formation of orbital **gliomas and meningiomas**. For a detailed description of the histology of the eye, the reader is referred to a simple, yet detailed and accurate account by Stevens and Lowe (1992).

THE EYELIDS AND EXTERNAL SURFACE OF THE EYE

Sampling Techniques

The **external surface of the eye and the eyelids** are accessible to **simple cytologic procedures**, within the reach of any ophthalmologist and any laboratory of cytology. **Scraping** the surface of the lesion under local anesthesia with an appropriate small instrument and **preparation of alcohol-fixed or air-dried smears is sufficient for the diagnosis of inflammatory disorders and some malignant lesions, such as carcinoma of the cornea and conjunctiva, or carcinomas of the eyelid** (Naib et al, 1967; Dykstra and Dykstra, 1969; Spinak and Friedman, 1977; Naib, 1970, 1981; Koss et al, 1992). Tsubota et al (1990) and Kobayashi et al (1991) advocated the use of a **modified small endocervical brush** with short, soft bristles (S-Brush, Medscan, Malmö, Sweden) for securing material from the conjunctiva. Instead of smears, these authors advocated the use of a cytocentrifuge and, more recently, ThinPrep (Cytoc Corp, Boxborough, MA) for processing of the samples (Kobayashi et al, 1997). Another brush with a spherical tip (Acellon-M) was used for the same purpose by Fujihara et al (1997).

Nolan et al (1994, 1997, 2001), described an ingenious technique named “**impression cytology**” for the study of conjunctival samples. Following local anesthesia, a **cellulose acetate strip** is placed on the surface of the cornea using gentle pressure, carefully peeled off, fixed in alcohol, and stained with Papanicolaou stain. The technique was used by other

investigators with impressive results (Dart, 1997; Divani et al, 1997).

Normal Cells in Conjunctival and Corneal Scrape Smears

The normal cell population in scrape smears consists of **squamous cells** of corneal origin and **cuboidal to columnar epithelial cells** of conjunctival origin. **Goblet cells** may be present (Fig. 41-1B). **In about 20% of the patients, squamous cell nuclei may display a central chromatin bar**, similar to the appearance of **Anitschkow cells**, first observed by Marner (1980). On scanning electron microscopy, the bars form a ridge in the nucleus, whereas in transmission electron microscopy, a tortuous folding of the nuclear membrane was observed (Kobayashi et al, 1992, 1998). Similar squamous cells have been observed in the oral cavity (see Chap. 21 and Fig. 21-1). Kumar and Manabati (1998) also observed **nuclear protrusions in the form of nipples in conjunctival cells**, a common finding in endocervical cells, discussed at length in Chapter 8. These nuclear variants may occur in health and disease and have **no diagnostic significance**.

Inflammatory Lesions

Viral Infections

Viral infections are very common and cause painful inflammation of the conjunctiva and the cornea. Their identification may be of substantial assistance in the clinical management of the patient. Naib et al (1967, 1972, 1981) have given excellent descriptions of **cytologic findings in eye disorders caused by viruses**. These are summarized in Table 41-1. The morphologic manifestations of various viral infections were described and illustrated in Chapters 10 and 19. Olding-Stenkivist and Brege (1975) applied immunofluorescent techniques for the diagnosis of herpetic conjunctivitis.

P.1510

There are now several other diagnostic techniques available, such as polymerase chain reaction (PCR) for viral identification.

TABLE 41-1 CYTOLOGIC CHANGES IN VIRAL INFECTIONS OF THE EYE AND ADNEXA

Disease	Ocular Site	Location of Inclusions	Inclusion: Descriptive Features	Remarks
Trachoma (chlamydia)	Cornea and conjunctiva	Cytoplasmic in mature cells	Multiple small (0.5 µm), basophilic with halos	Clusters of inclusions from necrotic cells
Inclusion conjunctivitis (frequent in newborn infants)		Cytoplasmic in mature cells	Same as above	Clusters of inclusions

Adenovirus	Conjunctiva	Intranuclear in small cells	Multiple, small eosinophilic, becoming coalescent, basophilic with halos	Few cells involved
Vaccinia	Conjunctiva	Cytoplasmic	Single, large, eosinophilic	
Herpes, simplex and zoster	Conjunctiva and cornea	Intranuclear, often in multinucleated cells with nuclear molding	Enlarged "ground-glass" nuclei forming eosinophilic inclusions	In herpes zoster multinucleated cells and eosinophilic inclusions are rare
Measles	Conjunctiva	Multinucleated giant cells	Multiple eosinophilic cytoplasmic inclusions with sharp halos	

(Modified from Naib ZM, et al. Exfoliative cytology as an aid in the diagnosis of ophthalmic lesions. Acta Cytol 11 :295-303, 1967; and Naib ZM. Cytology of ocular lesions. Acta Cytol 16:178-185, 1972.)

Chlamydial Infections

Conjunctival infection, caused by the bacterium, *Chlamydia trachomatis*, results in **trachoma**, the most widespread cause of blindness in the developing world. The infection, usually transmitted by human contact, leads to opacification of the upper part of the cornea and can be diagnosed by cytologic scraping. Besides trachoma, **chlamydia** may lead to various other less dangerous infections, such as **chronic inclusion conjunctivitis**, characterized by formation of lymphoid follicles in the conjunctiva and lower part of the cornea. As discussed above, Kobayashi et al (1991) advocated the use of the S-brush for the diagnosis of chlamydial infection.

The **cytology of the chlamydial infection** of the eye is identical to the infections in the female genital tract, described and illustrated in Chapter 10. Naib (1972) stressed the presence of **numerous small (0.5 µm) basophilic cytoplasmic inclusions with halos** as the characteristic cytologic finding (see Table 41-1). A number of staining techniques documenting this infection **in infants** was discussed and illustrated by Duggan et al (1986).

Other Inflammatory Processes

Allergic conjunctivitis, a common disorder, is characterized in smears by a large number of

eosinophils mixed with other inflammatory cells. Rivasi et al (1992) also observed an increase in goblet cells and the presence of various foreign materials, presumably of plant or mineral origin.

Bacterial infections result in acute conjunctivitis characterized by a **dominance of neutrophils** in smears. **Gonorrheal conjunctivitis** in newborn infants is a preventable disease with prophylactic treatment with antibiotics. A related organism, *Moraxella (Branhamella) catarrhalis*, an encapsulated diplococcus, may cause a purulent inflammation in adults. Eyelid infections with **staphylococci (sty)** rarely require cytologic confirmation. **Actinomycosis** of the cheek may spread to the orbit.

An occlusion of the meibomian ducts by an inflammatory process, usually secondary to inflammation of the hair follicles (**blepharitis**), may cause a **granulomatous inflammation** and **palpable enlargement** of the meibomian glands, known as **chalazion**. A chalazion may be mistaken for a tumor of the eyelids and, more importantly, **tumors may be mistaken for a chalazion**. Needle aspiration biopsy is the ideal diagnostic technique in these situations.

Mycotic infections are uncommon but may lead to a severe corneal disease and loss of vision, particularly with *Phycomycetes (Zygomycetes)*, such as **mucormycosis** (Johnson, 2000). These infections may cause sudden blindness (Downie et al, 1993). Other fungi, such as *Candida* and *Aspergillus* species, may be observed (Naib, 1981; Johnson, 2000). The morphology of these fungi is discussed at length in Chapter 19.

Parasites

Acanthamoeba

Corneal infection (keratitis) caused by *Acanthamoeba* species occurs with increasing frequency, mainly in **wearers of soft contact lenses** (Stehr-Green et al, 1989; Moore and McCulley, 1989).

P.1511

Corneal scrapings may be used for diagnosis (summary in Karayianis et al, 1988; Rivasi et al, 1995). Against a background of acute inflammation, trophozoites and the **double-walled cysts of the parasite** may be identified by several staining and fluorescent techniques, but also in Papanicolaou stain (Fig. 41-2). An early diagnosis and aggressive therapy are essential to prevent a loss of vision (Moore and McCulley, 1989; Rivasi et al, 1995).

Figure 41-2 Acanthamoeba in corneal epithelium in a young wearer of contact lenses. Small spherical cysts of the parasite are stained with Gomori-methenamine silver. (Courtesy of Dr. Pearl Rosenbaum, Montefiore Medical Center, Bronx, NY.)

Microsporidiosis

Microsporidial keratitis, caused by the tiny **intracellular protozoan parasite** of the genus ***Nosema*** or ***Encephalitozoon***, previously a rare event observed after corneal trauma in immunologically normal patients, is becoming increasingly **prevalent in HIV-positive**, immunosuppressed individuals (Wittner et al, 1993; Weber et al, 1994; Rasterelli et al, 1994; Coyle and Weiss, 1996). The epidemiology and life cycle of the parasite were summarized by Chen et al (2002). The parasite may be demonstrated in **conjunctival smears and biopsies** with various staining techniques or phase contrast microscopy (Fig. 41-3). Identification of specific genus is possible with electron microscopy, by a specific antibody or genomic analysis.

Figure 41-3 Microsporidia. *A.* Corneal scrapings from a 34-year-old man who was HIV-positive. The tiny organisms are present in the cytoplasm, surrounding a central clear area that is the nucleus. *B.* Biopsy of the limbal conjunctiva showing the Gram-positive organisms within the cytoplasm of the superficial epithelial cells. (Brown and Brenn stain.) (Courtesy of Dr. Pearl Rosenbaum, Montefiore Medical Center, Bronx, NY.)

Onchocerciasis (River Blindness)

Onchocerca volvulus is the largest of **human filariae**, transmitted by blackflies rather than mosquitoes (Ash and Spitz, 1945). It is the cause of **severe dermatitis** and **river blindness**, prevalent in Africa and parts of Central and South America, caused by numerous filariae accumulating in eye chambers, resulting in sclerosing keratitis. The disease is curable with appropriate drugs. To our knowledge, cytologic techniques have not been applied to the diagnosis of this very important disorder.

Echinococcosis

Sodhani et al (1996) described a case of echinococcosis affecting the eye. For description of this parasite, see Chapters 19 and 38.

Benign Tumors

Scrapings of benign tumors of the skin of the eyelids, such as **xanthelasma**, **molluscum contagiosum** (a viral disorder), and **squamous papillomas** may sometimes be of diagnostic advantage (Naib, 1981). In **xanthelasma**, lipid-filled cells may be observed. The cytologic presentation of **molluscum contagiosum** is discussed in Chapters 14 and 36. **Squamous papilloma** may show evidence of human papillomavirus infection in the form of squamous cells with abnormal nuclei and a large perinuclear clear zone, known as **koilocytes** (see Chap. 11 for extensive discussion of this entity). Other tumors occurring on the skin or surface of the eyelids are described in Chapter 36.

The **sebaceous meibomian glands** and the **small serous glands** located within the eyelids may be the site of **benign tumors mimicking tumors of the salivary glands, notably pleomorphic adenomas** (see Chap. 32). **Leiomyomas** of the eyelids have been described (Henkeind and Friedman, 1976).

P.1512

Malignant Tumors

Squamous Carcinoma and Its Precursors

Malignant epithelial tumors of **the conjunctiva** and **surface of the cornea** are predominantly **squamous carcinomas**, which in fortuitous situations, may be **diagnosed as preinvasive neoplastic lesions, such as carcinomas in situ** (Fig. 41-4B,D). The term **ocular surface squamous neoplasia (OSSN)** has been proposed to include intraepithelial and invasive squamous lesions (Lee and Hirst, 1995; Nolan et al, 1997). The spectrum of abnormalities ranged from “**simple dysplasia**” to **carcinoma in situ** to **invasive carcinoma**. Subsequently, Nolan et al used the term “**high-grade**” lesions for carcinomas in situ and related lesions. The presence of **human papillomavirus type 16**, determined by PCR, was reported in a substantial proportion of premalignant and malignant lesions of the conjunctiva and cornea (McDonnell et al, 1989). For further discussion of human papillomavirus, see Chapter 11. It has been reported that **conjunctival intraepithelial neoplasia commonly occurs in patients with AIDS** and may be a marker for this disease (Karp et al, 1996).

The **clinical presentation** of carcinoma in situ is often misleading. Slight **thickening of the conjunctiva combined with increased vascularity** may be mistaken for an inflammatory or degenerative lesion and treated as such by ophthalmologists. This was the experience of

Dykstra and Dykstra (1969), who used cytologic techniques for the diagnosis of squamous carcinoma of the conjunctiva. In **three of their eight cases, the lesion was still in situ and was not suspected clinically**. Nolan et al (2001) used touch preparations (**impression samples**—see methods of sampling) of the corneae in 267 patients and compared the cytologic samples with biopsies. In 231 of these patients, the lesions were preinvasive, and in several of these patients, there was **no evidence of clinical disease** (Hirst et al, 1998; Nolan et al, 2001). These observations from Australia, where corneal carcinoma is common in elderly people as a consequence of exposure to ultraviolet light, indicate yet another use of cytologic techniques in the detection of an important form of cancer, particularly in patients with AIDS.

Cytology of squamous carcinoma in situ of the cornea and conjunctiva is identical to similar lesions of the uterine cervix or oral cavity (see Chaps. 11 and 21) and consists of small to moderately sized atypical, or frankly malignant, squamous cells with markedly enlarged, hyperchromatic nuclei of variable sizes (Fig. 41-4A). Nolan et al (1997) stressed that in many of the preinvasive squamous lesions and in some invasive squamous carcinomas, there was **evidence of heavy keratinization** and the **cytologic presentation** of these lesions was **similar to the keratinizing variant of carcinoma of the uterine cervix** (Fig. 41-4C). In some of the invasive squamous carcinomas, the smear patterns were those of **poorly differentiated tumors** with little or no keratin formation and large nuclei containing large nucleoli.

There is limited knowledge on the **cytologic presentation** of **low-grade lesions** and it may be assumed they resemble similar lesions of the uterine cervix (see below and Chap. 11).

Dysplasia after Exposure to Mustard Gas

Safaci et al (2001) reported on several cases of **conjunctival dysplasia** in soldiers **exposed to mustard gas** during the Iraq-Iran war. The cells illustrated in this paper were reminiscent of low-grade squamous precancerous lesions of the uterine cervix (see Chap. 11). It is known that mustard gas has carcinogenic properties (Watson et al, 1989). Similar conjunctival lesions were designated as “keratitis” (Atkinson, 1946) or as “keratopathy” (Pleyer et al, 1999). It is not known whether these lesions are precursors of corneal carcinomas, therefore, follow-up information on Safaci's patients would be of great interest, particularly in view of the bioterrorist threat. **Nitrogen mustard**, a chemotherapeutic agent related to mustard gas, is a known lung carcinogen, as discussed in Chapter 20.

Malignant Melanomas

Malignant melanomas of the conjunctiva or the limbus may be related to benign nevi that occasionally occur in these locations. The differential diagnosis between an atypical nevus and a melanoma may be very difficult in biopsy material. To our knowledge, no attempts have been made to diagnose these lesions by scrape cytology. However, there are several reports of **melanomas of the eyelid**, diagnosed by aspiration biopsy (Arora et al, 1990; Gonidi et al, 1997). Cytology of uveal malignant melanoma is discussed below and in Chapter 34.

Carcinomas of Meibomian Glands

An **adenocarcinoma of meibomian glands**, thought clinically to represent a common inflammation of meibomian glands (chalazion) of the lower eyelid, was diagnosed on a scrape smear, showing poorly differentiated cancer cells of variable sizes (Fig. 41-5). Arora et al (1990) reported the results of **aspiration biopsy cytology of several tumors of the eyelid**, including **invasive squamous carcinoma** and **sebaceous carcinoma**. Sebaceous carcinoma

is the most common variant of cancer of meibomian glands, **fully capable of metastases** to neck lymph nodes or the parotid (Jakobiec and Chatlock, 1979; Sadeghi et al, 1999). The tumor is characterized by obvious cancer cells with the cytoplasm studded with small vacuoles representing lipids.

THE ORBIT AND THE EYE

Sampling Techniques

During the 1970s and 1980s, the **cytologic methods of diagnosis of diseases of the orbit and the eye** made great strides because of the developments of **new targeting techniques, such as computed tomography (CT) and ultrasonography, combined with the thin-needle aspiration biopsy (FNA)** (Dubois et al, 1979). To be successful, the method requires specialized equipment and skilled ophthalmologists, familiar with the intricate anatomy of this region. The aspiration procedure of the orbit is relatively simple and requires only local anesthesia. Aspiration of the eye is quite complex and requires an incision of the cornea or sclera. Special procedures have been used to aspirate lesions of the iris. The technical details of the procedure were previously described in detail and the interested reader is referred to the sources cited (Jakobiec et al, 1979; Engel et al, 1981, 1982; Char and Norman, 1982; Augsburger and Shields, 1984; Czerniak et al, 1985; Koss et al, 1992; Glasgow and Foos, 1993; Zeppa et al, 1997; Sen et al, 1999).

P.1513

Keratin-forming cancer cells, corresponding to the keratinized intraepithelial lesion shown in D. (Photographs courtesy of Dr. G.R. Nolan and Prof. L.W. Hirst, Royal Brisbane Hospital, Brisbane, Australia.)

Figure 41-5 Carcinoma of meibomian glands, clinically mistaken for a chalazion. *A*. Scrape smear of the lesion containing numerous cancer cells, singly and in clusters. *B*. Biopsy of the lesion showing a duct replaced by cancer cells and areas of invasive carcinoma. (Case courtesy of Dr. Clifford Urban, Phoenixville, PA.)

P.1514

The rare **complications** of the procedure include intraorbital hemorrhage and scar formation that may result in optic neuropathy and limitation of ocular mobility.

Lesions of the Orbit

Clinically, the space-occupying lesions of the orbit **may cause dysfunction of ocular motility, ptosis of the eyelids, proptosis (protrusion of the eye), and considerable visual difficulties**. These symptoms may be caused by a variety of disorders, ranging from orbital inflammation to tumors.

Benign Nonneoplastic Lesions Inflammatory Lesions

Inflammatory lesions may be caused by **bacterial infections** leading to an acute inflammation of orbital connective tissue, or a cellulitis. **The aspirates** of the orbit in such cases yield predominantly polymorphonuclear leukocytes, accompanied by necrotic tissue fragments. The lesions may also be caused by **fungi**, mainly *Aspergillus* species, but occasionally by other organisms as well (Cangiarella et al, 1996). **Granulomatous lesions, either tuberculosis or sarcoidosis**, may be observed (Hoover et al, 1986). Very rare cases of orbital involvements by **Langerhans' cell histiocytosis** were also reported (Kramer et al, 1997; Nassar et al, 2000). For description of cytologic presentation of these entities, see Chapters 19 and 31.

Benign Tumors and Tumor-Like Disorders

Among the benign orbital lesions of note are:

- Cysts
- Benign tumors of lacrimal glands
- Inflammatory pseudotumors
- Meningiomas and benign gliomas of optic nerve

Foreign body granulomas (Iyer et al, 1998) and **displaced benign lacrimal tissue** (Boccatto et al, 1992) may mimic tumors of orbit.

With the exception of meningiomas and benign mixed tumors (pleomorphic adenomas) of the lacrimal glands, the aspirates of benign lesions are usually scanty and great care is required to preserve the material.

Orbital Cysts

These may be **mucocoeles**, probably derived from lacrimal glands and lined by cuboidal or columnar mucus-producing cells. The very rare **enterogenous type cysts** are lined by benign cuboidal glandular cells. The cyst content may show high levels of carcinoembryonic epithelial antigen (CEA), as described by Ballesteros et al (1997). **Dermoid cysts**, characterized by acellular keratin debris, have also been reported (Arora et al, 1992).

Benign Tumors of the Lacrimal Glands

These are commonly **pleomorphic adenomas** with a cytologic presentation identical to that of salivary gland tumors (see Chap. 32). A **pigmented pleomorphic adenoma** of the ciliary body, mimicking a malignant melanoma, was described in the cytologic sample by Laver et al (1996). Boccato et al (1992) pointed out that **normal ectopic lacrimal glands** may be mistaken for a neoplasm.

Meningiomas

Meningiomas of the orbit may occur secondarily as an extension of **intracranial meningiomas** but may also be **primary**, derived from meningotheial cells accompanying the optic nerve. The benign tumors can be recognized cytologically by **whorls** of cells with abundant cytoplasm, known as **meningotheial cells, often accompanied by psammoma bodies**. The small tumor cells may also form cohesive flat clusters (Fig. 41-6) (Cristallini et al, 1990; Koss et al, 1992; Cangiarella et al, 1996). For further description and illustrations of cytology of this tumor, see Chapter 42.

Gliomas of the Optic Nerve

These exceedingly rare tumors are usually observed during the first decade of life and are **known as juvenile pilocytic astrocytomas** (Marquardt and Zimmerman, 1982). Cytology of these tumors was described by Kennerdell et al (1979, 1980) and by Koss et al (1992).

Elongated cells with bland nuclei against a fibrillary background were observed.

Gliomas may also occur in patients with **neurofibromatosis**.

Other Benign Tumors

Leiomyomas of the orbit were described by Jakobiec et al (1975).

Pseudotumors

Inflammatory pseudotumors are acute and chronic **inflammatory disorders** affecting intraorbital tissues (Blodi and Gass, 1967). Another type of pseudotumor (**idiopathic pseudotumor**) is a nonspecific inflammatory reaction with occasional formation of **granulomas** and fibrosis. The acute inflammatory disorders are readily recognized clinically, as discussed above.

The lesion that may cause significant diagnostic difficulties is the **benign lymphoid pseudotumor, yielding cytologic material composed of a spectrum of lymphoid cells, showing various stages of maturation, not unlike a hyperplastic lymph node** (Arora et al, 1992; Cangiarella et al, 1996). The aspirate usually does not permit a secure differentiation

between a benign, follicle-forming lymphoid lesion and a **malignant lymphoma**. In any event, even the fate and the significance of the lymphoid pseudotumor are not secure and in at least some cases, a malignant lymphoma develops with the passage of time (Jakobiec, 1978; Brady et al, 1982). Flow cytometry and immunocytology, to determine

P.1515

the clonality of the disorder, may be applied to orbital aspirates, as described below (Nassar et al, 2000).

Figure 41-6 Meningioma of orbit. Aspirate. *A.* Typical field of a smear of meningeoma showing medium-sized cells forming concentric whorls. *B.* A flat sheet of cells with clear cytoplasm and small nuclei, some showing small nucleoli. Some nuclei show intranuclear cytoplasmic inclusions. (Photographs courtesy of Dr. Joan Cangiarella, New York University, New York.)

Malignant Tumors

The principal malignant tumors occurring in the orbit are:

Tumors of lacrimal glands

Adenoid cystic carcinoma

Adenocarcinoma

Malignant tumor ex pleomorphic adenoma or malignant mixed tumor

Rare tumors

Malignant lymphomas

Sarcomas (rare)

Children: embryonal rhabdomyosarcomas

Adults: sarcomas of muscle, connective tissue or vessels

Tumors invading the orbit from adjacent sites (i.e., nasal sinuses, parotid)

Metastatic tumors (see end of chapter)

Malignant Tumors of Lacrimal Glands

We and others (Sturgis et al, 2001) have observed reported cases of examples of **adenoid**

cystic carcinoma. De Rosa et al (1986) and Rosenbaum et al (1995) reported cases of **acinic cell carcinoma.** The histology and cytologic presentation of these tumors is discussed at length in Chapter 32.

We have also observed two patients with **malignant tumors ex pleomorphic adenomas (malignant mixed tumors)**, which share the morphologic features with the corresponding tumors of salivary glands. These uncommon tumors are best recognized by the presence of **two cytologic patterns side by side, one with features of a benign pleomorphic adenoma and the other a malignant tumor that can be a carcinoma or, very rarely, a sarcoma.** In one of the cases seen by us, the dominant cytologic pattern of the malignant component of the tumor was an adenocarcinoma. The initial biopsies disclosed a benign mixed tumor. The documentation of the malignant nature of the tumor required several additional biopsies (Fig. 41-7). Similar cases have been reported by Arora et al (1992), Das et al (1994), Cangiarella et al (1996), and Dávila et al (1998).

A case of **mucoepidermoid carcinoma** of the lacrimal gland has been reported by Das et al (1994).

Malignant Lymphomas and Related Lesions

Malignant lymphomas of the orbit became more frequent with the onset of AIDS. These are **non-Hodgkin's lymphomas**, usually of B-cell type, that have the same characteristics as primary malignant lymphomas, described in Chapter 31 (Ling et al, 1988; Cangiarella et al, 1996; Laucirica and Font, 1996; Weber et al, 1996). Zeppa et al (1997) and Nassar et al (2000) suggested that **flow cytometry** and **immunocytochemistry** may be used on orbital aspirates to identify monoclonal (malignant) from polyclonal (benign) populations of lymphoid cells and thus separate true lymphomas from inflammatory pseudotumors (see above). An example of large cell lymphoma of the orbit in vitreous fluid is shown in Figure 41-11. Nassar et al (2000) reported three cases of primary **orbital plasmacytoma**.

Sarcomas

Embryonal rhabdomyosarcomas are observed in children. Arora and Betharia (1994) described the smears as composed of **medium-size cancer cells without cytoplasmic striations.** The cells were positive for neuron specific enolase and desmin. We observed an aspirate of a sarcoma, not further classified, involving the orbit in an 82-year-old woman with Paget's disease of bone. The aspirate contained a few malignant cells, insufficient to determine tumor type. The cytology of these tumors is discussed in Chapter 35.

THE EYE

As discussed above, the aspiration biopsy of the eye is a technically difficult procedure best performed by qualified

P.1516

ophthalmologists. Sen et al (1999) proposed that the cell sample may be obtained by direct route across the eye rather than via the orbit. Usually the preliminary diagnosis of the space-occupying lesion is suggested on clinical grounds and the aspiration biopsy serves to confirm the clinical impression. The **repertoire of primary eye space-occupying lesions is fairly limited.**

Figure 41-7 Malignant mixed tumor (malignant tumor ex pleomorphic adenoma) of a lacrimal gland in a 68-year-old male. *A,B.* Aspirate stained with Papanicolaou (*A*) and Diff-Quik (*B*), showing large malignant cells, some in papillary configuration and some of cuboidal or columnar shape, suggestive of adenocarcinoma. *C.* Original biopsy of the orbital mass showing a benign pleomorphic adenoma. *D.* Second large biopsy disclosed the presence of duct-forming adenocarcinoma.

Benign Lesions

Case reports describing the cytology of benign processes within the eye are exceedingly rare. Stewart et al (1993) described the findings of an uncommon congenital abnormality of the eye known as **Coats' disease** (Chang et al, 1984). The sediment contained numerous “**pigmented bodies**” of unknown derivation and **cholesterol crystals**.

Bilateral Diffuse Melanocytic Proliferation

This unusual **paraneoplastic syndrome** occurs mainly in patients with gynecologic cancer and consists of a **benign proliferation of uveal melanocytes** forming nodules in the iris and choroid. The patients also develop cataracts and retinal detachment (Barr, 1982; recent summary in Chahud et al, 2001). Although there is no record of cytologic evaluation of these uncommon lesions, they may well enter into the differential diagnosis of primary ocular melanoma.

Malignant Tumors

The most common malignant tumors are **retinoblastomas** in children and **malignant melanomas** in adults.

Retinoblastoma

Retinoblastoma originates in the retina. This highly malignant tumor can be unilateral or bilateral and affects mainly children in the first 2 years of life. The tumor has very interesting implications in genetics and molecular biology of cancer. For a discussion of the **retinoblastoma gene (*Rb* gene)**, see Chapter 7.

Aspiration biopsy of a retinoblastoma yields cells and cell rosettes that **cannot be distinguished on morphologic grounds from cells of related tumors, neuroblastomas** (see Chap. 40) or **medulloblastoma** (see Chap. 27). An example of metastatic neuroblastoma to the orbit is shown in Figure 41-12. Several such cases were reported by Das et al (1989), O'Hara et al (1993), Arora and Betharia (1994), Sen et al (1999), and a case in an older child by Decaussin et al (1998).

Malignant Melanoma

Histology

Melanomas are the most common primary intraocular malignant tumors, occurring mainly in adults. These tumors

P.1517

may originate in the **uvea, choroid, iris, or ciliary body** and are thus sometimes collectively referred to as **uveal melanomas** (Czerniak et al, 1983; Char et al, 1989; Koss et al, 1992; Shields et al, 1993). The tumors are subclassified into **spindle-cell types A and B** and **epithelial type** (McLean et al, 1982). The **prognosis** is distinctly more favorable with **spindle-cell type melanoma type A**, composed of slender tumor cells, often with **nuclear folds (creases)** along the long axis of the nucleus, and small nucleoli. The **type B** spindle cell melanoma is composed of bundles of clearly malignant spindly cells, some containing deposits of melanin. The **epithelial type melanomas** are composed of obvious malignant cells, usually with abundant pigment formation.

Cytology

The most difficult to recognize are cells of the **type A spindly melanoma**. The aspirates contain a fairly monotonous population of small, spindly cells with slender cytoplasmic extensions, resembling smooth muscle cells. The oval nuclei of such cells are **granular**, contain small but clearly visible **nucleoli**, and show **prominent nuclear creases**. Pigmented cells are relatively few (Fig. 41-8A,B). **In type B spindly ocular melanoma**, the aspirates contain abundant cancer cells forming bundles. The cells are larger than in type A and have long **fragile bipolar cytoplasmic processes**. The **nuclei** are **hyperchromatic**, coarsely granular and provided with **large nucleoli**. Intranuclear cytoplasmic inclusions have been observed (Koss et al, 1992).

Figure 41-8 Melanomas of the eye. Aspiration smears and corresponding histology. *A,B.* Spindle-cell melanoma, type A. The aspirate (*A*) shows sparse spindly cells with finely granular nuclei, tiny nucleoli, and nuclear creases. The corresponding tumor of the choroid is composed of bundles of spindly cells. *C,D.* Carcinomatous melanoma. The smear (*C*) is composed of obviously malignant mononucleated and multinucleated cells, some containing cytoplasmic pigment. The corresponding tumor (*D*) was a carcinomatous melanoma. (Both cases courtesy of Dr. Jacek Sygut, Oncology Institute, Kielce, Poland.)

Melanoma of the epithelial type is the easiest to recognize. **Large polygonal or approximately spherical tumor cells**, usually containing abundant melanin pigment, are easily identified. Many of these tumors shed oddly-shaped, heavily **pigmented tumor cells** in which the nucleus cannot be visualized (Fig. 41-8C,D). Other cells, however, display morphologic features characteristic of malignant melanoma: cells with **marked nuclear abnormalities, multinucleated cells, and intranuclear cytoplasmic inclusions**. **Bipolar pigmented cells and cells resembling dendrites with multiple cytoplasmic extensions** also occur in ocular aspirates (Koss et al, 1992). The very **rare paraneoplastic syndrome of diffuse melanocytic proliferation** (see above) must be considered in the differential diagnosis of malignant melanoma.

An interesting feature of ocular malignant melanoma is the propensity of these tumors to form **delayed liver metastases**,

P.1518

sometimes 20 or more years after the removal of the primary tumor. This writer (LGK) called this the “**syndrome of a glass eye and protuberant abdomen**” (see Chap. 38).

THE VITREOUS BODY

From time to time, the semi-solid vitreous body may be removed by vitrectomy or aspirated to clarify the cause of an intraocular opacity (Green, 1984). The semisolid material is centrifuged and the sediment prepared as cytopsins and cell blocks (Engel et al, 1982; Mandell et al, 1987).

Lin et al (1999) divided the lesions in three groups: **inflammation and infections, hemorrhage, and malignant tumors**, mainly malignant lymphomas. In a summary of results of

74 vitreous fluid specimens from 60 patients, these authors concluded that **inflammatory or infectious processes**, observed in 41 patients, are most common. A broad array of microorganisms, including **bacteria, fungi, and viral infections**, were observed. The second group of diagnoses was **hemorrhage**, observed in 12 patients, and the third, smallest group was caused by **malignant lymphomas** (7 patients). **Fibrovascular membranes**, observed in diabetic retinopathy, and retinal fragments were reported by Mandell et al (1987).

In the absence of inflammation or tumor, Koss et al (1992) observed that **benign pigmented, melanin-containing cells, probably derived from the uvea, and macrophages**, may be observed in the vitreous. **Small, slender columnar cells with eosinophilic cytoplasm**, known as **hyalocytes**, may also be observed (Fig. 41-9). The origin or role of the hyalocytes is unknown (Spencer, 1996).

Asteroid hyalosis is a condition in which minute spherical structures, composed of calcium soap, may cause an opacification of the vitreous body (Spencer, 1996). A cytologic diagnosis of this condition was reported by Loughman and Lin (1995). **Spherical bodies** measuring from 30 to 80 μm in diameter and showing central birefringent crystalline particles were observed.

In **retinal detachment**, fragments of the retina may be observed (Fig. 41-10) (Koss et al, 1992). Also, fragments of the lens in the form of crystalline material may occur (Mandell et al, 1987).

Figure 41-9 Vitreous hyalocytes. Cell content of vitreous fluid aspirated because of intraocular opacity. Elongated small epithelial cells with eosinophilic cytoplasm (hyalocytes) in company of a few lymphocytes and pigmented cells.

Figure 41-10 Fragment of retina in vitreous fluid in retinal detachment.

Cells derived from uveal tumors may desquamate into the vitreous. We observed several cases of **malignant melanoma and malignant lymphoma**, the latter either in the elderly or in patients with AIDS, easily recognizable by the morphology of the dispersed cells, and confirmed by immunostaining with common lymphocyte antigen (Fig. 41-11). Farkas et al (2004) recognized malignant lymphoma in the vitreous fluid in 9 of 13 samples. It is of note that only 3 of these patients had generalized lymphoma. Hence, it must be assumed that several of these ocular lesions represent primary ocular lymphomas. The cytologic presentation of these tumors was discussed above and in Chapter 31.

METASTATIC TUMORS TO THE EYE AND ORBIT

Ferry and Font (1974, 1976) and Font and Ferry (1976) described their observations with nearly 300 malignant tumors metastatic to the eye and adnexa. Surprisingly, these authors reported that **most metastases are found in the posterior portion of the eye and relatively few in the anterior part of the eye or the orbit.**

In our experience, the malignant tumors to the orbit or the eye that are most commonly aspirated are metastases from other organs. Usually, the primary site of the tumor is known, but occasionally, it may be occult and the orbital lesion is the first manifestation of disease.

In **infants and children, metastatic neuroblastoma** is the most common orbital tumor (Koss et al, 1992; Arora and Betharia, 1994). Protrusions of the eye and sometimes radiologic abnormalities of the skull ("sun ray" appearance of bony spicules) occur fairly often. Metastatic neuroblastoma is probably the **most common source of clinical diagnostic errors** in eye lesions in childhood, **as they may be mistaken for lymphoblastic leukemia** or even **thalassemia major**. In a case reported from our laboratories, the orbital

P.1519

lesion in a 3.5-year-old girl was initially thought to represent acute lymphoblastic leukemia (Slamovits et al, 1991). Morphologically, neuroblastomas are **identical to primary retinoblastomas** of the eye globe, which can be recognized by ophthalmologic (or

fundusoscopic) examination (Arora and Betharia, 1994). Cytologically, the small tumor cells in both tumors form the characteristic **rosettes filled with delicate neurofibrils** (Fig. 41-12). Other small cell tumors of childhood, such as **Ewing's sarcoma** and **embryonal rhabdosarcoma**, may occasionally involve the orbit.

Figure 41-11 Malignant lymphoma in vitreous fluid. The aspirate shows a monotonous population of dispersed atypical lymphocytes. Nuclear abnormalities are better appreciated in *B* under high magnification.

In adults, the origins of metastatic tumors to the orbit are diverse and include every conceivable primary site. In our experience, **mammary carcinoma** is the most common metastatic tumor in women. The primary site can be recognized if the small “signet ring” cancer cells show the **cytoplasmic vacuoles with a central condensation of mucus** (magenta or target cells, see Chap. 29), characteristic of lobular carcinoma (Fig. 41-13A). In men, we have seen examples of metastatic **lung cancer** and **prostatic carcinoma** (Fig. 41-13B). In the latter case, the precise diagnosis could be established by a positive stain for prostate specific antigen. In Ferry and Font's experience (1974), **tumors of the gastrointestinal tract origin** are also commonly observed in the eye. A case of **occult primary esophageal adenocarcinoma with orbital metastasis as the first manifestation of disease** in a 61-year-old female patient, was reported from this laboratory by Cangiarella et al (1996). The tumor was diagnosed in **washings of the vitreous** (Fig. 41-13C,D). We also observed metastatic **squamous carcinoma** from the skin of the forehead and an orbital extension of a **chondrosarcoma** of the nasal cavity. Heerema and Sudilovsky (2001) reported a case of mucinous **ovarian** adenocarcinoma metastatic to the orbit. Logrono et al (1997) described a case of metastatic **leiomyosarcoma**. In our experience, orbital and eye involvement in **leukemias and generalized malignant lymphomas** is not uncommon, as confirmed by others (Weber et al, 1996; Nassar et al, 2000). Yakulis et al (1995) described a case of **multiple myeloma**

P.1520

metastatic to the orbit in a young man with formation of **amyloid** that could be recognized in the aspirate.

Figure 41-12 Metastatic neuroblastoma. Aspirate of orbit in a 3 1/2-year-old girl with referral diagnosis of acute lymphoblastic leukemia. *A*. Small, monotonous malignant cells surrounding spherical empty spaces, corresponding to tumor rosettes. In *B*, the fibrillar core of a rosette stains pink. Special stains disclosed the presence of neurofibrils in the center of the rosettes (not shown). (*A*: Pap stain, *B*: Diff-Quik.)

Figure 41-13 Metastatic carcinomas to orbit. *A*. Mammary lobular carcinoma in a 64-year-old woman. The tumor derivation and type can be easily established because of small cells of "signetring" configuration and condensations of mucus in the center of the large cytoplasmic vacuole (see Fig 29-37). *B*. Metastatic pulmonary adenocarcinoma in a 60-year-old man. The origin of the tumor could not be determined on morphology alone. *C*. Metastasis from occult adenocarcinoma of esophagus in washings of the vitreous. *D*. Esophageal tumor corresponding to *C*. (*C,D*: Courtesy of Dr. Joan E. Cangiarella, New York University, New York.)

Acknowledgment

I thank Dr. Pearl Rosenbaum, Professor of Pathology and Ophthalmology, Albert Einstein College of Medicine, and Head of the Ophthalmic Pathology Laboratory at Montefiore Medical

Center for her insightful comments and many suggestions pertaining to this chapter.

42

The Central Nervous System

Leopold G. Koss

Carlos A. Rodriguez

The identification of the nature of space-occupying lesions of the brain and adjacent organs located within the skull took a giant step forward with the introduction of **computed tomography** (CT), which allowed precise localization and sizing, and thus better sampling, of space-occupying lesions in vivo. With growing experience, the benign or malignant nature of these lesions could be determined radiologically in most, but not all, cases. **Magnetic resonance imaging** (MRI) provides additional visual information on the nature of the lesions of the central nervous system (CNS) with a still higher level of accuracy.

Cytologic techniques have been used for diagnosis of brain lesions since 1930, when Eisenhardt and Cushing advocated the use of **touch preparations** for rapid diagnosis of tumors. A major refinement in this regard occurred with the introduction of stereotactic CT machines that allowed an accurate placement of thin needles in the space-occupying lesions of the brain and led to the development of diagnostic aspiration techniques (Backlund, 1971). This approach requires only a small burr hole that usually can be performed under local anesthesia and, thus, is less traumatic to the patient than a craniotomy. Seliem et al (2003) reported successful thin-needle aspiration biopsies of brain lesions through a 5-mm burr hole.

The issue of cytologic sampling of the lesions of the CNS with a minimum of trauma became even more important with the onset of AIDS because most of the lesions in these patients are of an infectious nature requiring conservative treatment (Cajulis et al, 1997). Still, the aspiration technique requires considerable manual dexterity and is, therefore, limited by the interest and skills of the neurosurgeons, some of whom still prefer to perform diagnostic craniotomies, particularly in the presence of a suspected tumor. The issue of **accuracy** of cytologic diagnosis of CNS lesions has been discussed by several groups of investigators. There appears to be a general agreement that the method has a specificity and sensitivity close to 90% (Barnard, 1981; Liwnicz et al, 1982; Silverman et al, 1986; Cappabianca et al, 1991; Torres and Collaco, 1993; see also an extensive summary in Liwnicz et al, 1992). Other observers suggested

P.1524

that a **combination of cytologic preparations and frozen sections** is likely to provide still better diagnostic results (Burger et al, 1991; DiStefano et al, 1998). Regardless of these considerations, most pathologists confronted with an **intraoperative consultation** on a brain lesion are likely to prepare a **smear or a crush preparation** of the submitted tissue sample, which often may be too small or fragile for a frozen section. For these reasons, **cytology of the CNS has become of capital importance in neuropathology**. This chapter offers an overview of principal cytologic manifestations of infectious diseases and tumors of the brain but cannot claim to be exhaustive, because of the extreme rarity of some lesions that have not

been seen by us.

METHODS OF PROCESSING OF BRAIN SAMPLES

The material obtained either by aspiration biopsy or by tissue sampling can be processed as **smears or small tissue fragments (minibiopsies or cell blocks)**. The advantage of cell blocks is the option of using multiple special stains on the same sample, whereas this is much more difficult with smears (Liwnicz et al, 1982, 1992).

Barnard (1981) advocated the use of **1% toluidine blue stain** on wet smears as very rapid and adequate for most diagnostic decisions. In more recent times, popular stains such as **Diff-Quik** for rapid examination of unfixed smears or **Papanicolaou stain** for fixed smears have been used. For description of these stains and their use, see Chapter 44.

NORMAL BRAIN

Anatomy

The central nervous system is a very complex structure containing a variety of normal cell types. It is beyond the scope of this book to describe the anatomy and histology of the brain and the reader is referred to the appropriate standard textbooks. For the purpose of this chapter, only a brief description of salient features is provided.

The brain is a fragile organ that is protected externally by the skin and bones of the skull and internally by a rigid membrane, known as the **dura mater** and the **subarachnoid space**, limited by the **pia and the arachnoid membranes**, filled with cerebrospinal fluid. (For description and discussion of the origin and function of the cerebrospinal fluid in health and disease see Chap. 27.)

The brain is composed of three parts:

- The cerebral hemispheres
- The brain stem
- The cerebellum

The cerebral hemispheres, cerebellum, and the brain stem enclose a **central space (ventricles) filled with cerebrospinal fluid**. The **lateral ventricles** are located in the hemispheres, the **third ventricle** is located in the cerebral midline, and the **fourth ventricle** is surrounded by the brain stem and the cerebellum. **The cerebellum** is separated from the cerebral hemispheres by a fold of the dura, known as the **tentorium**. **The pineal gland** is found at the level of the posterior wall of the **third ventricle**. The **pituitary gland** is found on the lower surface of the anterior part of the brain in a cavity formed by the skull, known as **sella turcica**. For a concise and lucid summary of anatomy of the CNS, see Rosenblum, 1996.

Cytology

The Neurons (Ganglion Cells)

The **neurons, or ganglion cells**, are the principal component of the central nervous system and account for brain functions. Most neurons are **very large cells, measuring up to 40 µm in diameter, that are provided with cytoplasmic processes** of various lengths. The numerous shorter processes, known as **dendrites**, provide communication among neurons by means of complex electrochemical signals, resulting in discharge of substances known as

neurotransmitters. The neurons are also provided with one long process known as **axon** that provides long distance communication with peripheral organs. The demonstration of cytoplasmic processes requires special stains.

All neurons have **very large nuclei** (up to 18 μm in diameter) and frequently **prominent, large nucleoli**. Rough endoplasmic reticulum, known as **Nissl's substance**, may obscure the nucleus and is present in the cytoplasm of many neurons. The neurons show an enormous **diversity of morphologic configurations** (Liwnicz et al, 1992). Examples of neurons are shown in Figure 42-1.

Glial Cells

The neurons are surrounded by a supporting apparatus, the glial cells, subdivided into **astrocytes, oligodendroglia, and ependymal cells**. The dominant cells are the **astrocytes**, relatively small star-like cells, with scanty cytoplasm provided with numerous processes, spreading in all directions. The normal astrocytes cannot be well visualized without special stains but stand out in the so-called **reactive gliosis**, when they proliferate because of an injury to the brain, such as an infarct (Fig. 42-2).

Oligodendroglias are small glial cells with scanty cytoplasm and few processes. These cells cannot be recognized without special stains. In tumors, the oligodendroglial cells may surround ganglion cells in a process known as **satellitosis**. Their morphology is evident in oligodendrogliomas (see below).

Ependymal cells, lining the ventricular system, are **small columnar or cuboidal epithelial cells** with spherical small nuclei. The cells generally form flat sheets, wherein the cell borders can be readily identified (Fig. 42-2C).

Other Cells

Cells of the **choroid plexus**, responsible for the formation of the cerebrospinal fluid, were discussed at length in Chapter 27. These cells are **morphologically similar to ependymal**

P.1525

cells (see Fig. 42-2D). Cells of **meningeal and blood vessel origin** may be observed in brain aspirates but are very difficult to identify.

Figure 42-1 Neurons. *A,B.* Pyramidal neuron from the motor cortex surrounded by small nuclei of astrocytes and somewhat larger nuclei of oligodendroglial cells. *C.* Motor neuron from the spinal cord. The cytoplasm is filled with Nissl substance, obscuring the nucleus. *D.* Purkinje neuron from the cerebellum. Note the distinct shape of the cell resembling an octopus. The neuron is surrounded by nuclei of small glial cells.

LESIONS OF THE CENTRAL NERVOUS SYSTEM

Virtually all patients who are referred for a diagnostic workup are symptomatic. The fundamental questions that must be answered on the basis of the cytologic preparation are:

- Is the lesion benign or malignant?
- If the lesion is benign, can it be treated?
- If the lesion is malignant, is it a primary tumor or a metastasis?
- Is the malignant lesion amenable to treatment?

The task of the cytopathologist is comparatively easy if the make-up of the smear is suggestive of an inflammatory process or of a malignant tumor of high grade. The **difficulties occur with marked inflammatory reaction that may mimic a malignant lymphoma and with low-grade astrocytomas that may mimic reactive gliosis and vice versa.** The recognition of metastatic tumors is usually, but not always, comparatively easy, particularly if supported by clinical and imaging data.

INFLAMMATORY LESIONS OF THE BRAIN

Table 42-1 lists the principal inflammatory lesions of the brain, most of which were extremely rare prior to the onset of AIDS. Today, however, these lesions can be observed in many immunocompromised patients who have symptoms suggestive of CNS disorders (Zimmer et al, 1992; Cajulis et al, 1997).

Lesions Caused by Viruses

Encephalitis

These are diffuse diseases of the brain caused by a variety of viruses (**equine, St. Louis, West Nile, tick-borne, human immunodeficiency virus [HIV], etc.**) that do not form focal lesions and are, therefore, not amenable to cytologic evaluation. These diseases may cause changes in cerebrospinal fluid (CSF) (see Chap. 27). A particularly good account of quantitative and qualitative sequential changes in CSF

P.1526

in tick-borne encephalitis was presented by Jeren and Vince (1998). The diagnosis of encephalitis practically never requires an aspiration biopsy of the brain.

Figure 42-2 Glial, ependymal and choroid plexus cells. *A,B.* Large glial cells in reactive gliosis showing multiple cytoplasmic processes. *C.* A cohesive cluster of small cuboidal ependymal cells. *D.* A cluster of choroid plexus cells with vacuolated cytoplasm and centrally located small nuclei. Note similarity to ependymal cells. (*B:* Phosphotungstic acid stain.)

Herpes Simplex Virus, Cytomegalovirus, and Varicella-Zoster Virus

Viral infections of the brain may form localized lesions that may require diagnostic intervention. Particularly important is **herpesvirus and varicella-zoster infections** that may cause **tumor-like hemorrhagic necrosis** of the brain. The cytologic manifestations of these disorders have been repeatedly described in this book (particularly in Chaps. 10, 19, and 27) and need not be repeated here. The recognition of the characteristic **nuclear or cytoplasmic inclusion bodies** is diagnostic of these disease processes. In many instances, the diseases can be diagnosed by polymerase chain reaction (PCR) of the CSF.

Measles

Previously extremely uncommon and observed only in children, **delayed or subacute measles encephalitis** (also described as **measles inclusion body encephalitis**), has become an important cause of CNS infection in AIDS, usually with a fatal outcome (Budka et al, 1996). The disease may cause focal lesions and is therefore diagnosable by stereotaxic aspiration smears. In a few case reports, the presence of **large eosinophilic nuclear inclusions** in neurons was described (Kim et al, 1992; Poon et al, 1998).

Multinucleated giant cells and cytoplasmic inclusions, commonly observed in acute measles, were not observed in the brain.

Progressive Multifocal Leukoencephalopathy

This previously very rare brain disorder, caused by **human polyomavirus type JC**, has become one of the most common afflictions of the brain in immunocompromised patients (Cajulis et al, 1997; Greenlee, 1998). The first report of cytologic diagnosis of this disease was

by Suhrland et al (1987) who observed the classical **basophilic intranuclear inclusion bodies** in oligodendroglial cells (Fig. 42-3). For further description of this family of viruses and illustration of the cytologic effects of polyomavirus infection in the urinary tract, see Chapter 22. The diagnosis can be confirmed by immunostaining with an antigen to the related SV 40 virus or by PCR of the CSF (Silver et al, 1995; Fong et al, 1995; d'Arminio Monforte, 1997).

Lesions Caused by Bacteria

For the most part, these lesions are **brain abscesses** that may be caused by a variety of microorganisms. Few, if any,

P.1527

brain abscesses are aspirated. In smears and squash preparations, pus and cell debris have been observed (Liwnicz et al, 1992). See also changes in spinal fluid, described in Chapter 27.

TABLE 42-1 INFLAMMATORY PROCESSES AFFECTING THE BRAIN

Viruses

- Encephalitis (various types)
- Herpes simplex virus
- Cytomegalovirus
- Varicella-zoster
- Measles
- Human polyomavirus
- Progressive multifocal leukoencephalopathy

Bacteria

- Abscesses (various species)
- Mycobacterium tuberculosis*
- Mycobacterium avium*
- Spirochetes
- Spirochaeta pallida* (syphilitic gumma)

Fungi

Cryptococcus

Candida species

Aspergillus

Other mycoses

Protozoa

Toxoplasma gondii

Ameba histolytica

Trypanosoma cruzi (Chagas' disease)

Paragonimus westermani

Helminths (worms)

Strongyloides stercoralis

Tenia solium (cysticercosis)

Many of these disorders, previously very rare, have become very common in immunosuppressed patients with AIDS.

To our knowledge, there are no recorded experiences with cytology of brain lesions caused by **mycobacteria**.

Spirochetes***Syphilis***

Syphilis, a sexually transmitted disease caused by ***Spirochaeta pallida***, may cause various disorders of the CNS in its final, **or tertiary, stage**. One of these complications is a tumor-like granulomatous inflammation of the brain, known as **gumma**. To our knowledge, there are no published records of cytology of these lesions, which have become exceedingly rare.

Lyme Disease

The cytopathologic manifestations of this disease, caused by tick-transmitted spirochete, ***Borrelia burgdorferi***, are discussed in Chapter 27.

Lesions Caused by Fungi

The organisms affecting the brain are the same as in cerebrospinal fluid, discussed in Chapter 27. ***Aspergillus*** and related species of fungi may cause **infarcts** of the brain by invasion and occlusion of blood vessels. Deshpande and Munschi (2000) reported a case of rhinocerebral **mucormycosis**.

Figure 42-3 Multifocal leukoencephalopathy. The classic, large basophilic intranuclear inclusions in oligodendroglial cells are diagnostic of this disease. These cells are morphologically identical to those observed in the urinary sediment (see Chap. 23).

Lesions Caused by Protozoa

Toxoplasma gondii is a ubiquitous protozoan parasite that has been initially observed in small children whose eyes and brain are chiefly affected. With the onset of AIDS and immunosuppressive therapy, the cerebral form of the infection in adults has become much more common. In AIDS, the organism can cause fatal necrotic brain lesions. Cajulis et al (1997) observed that toxoplasmosis is the second most common infectious brain disorder in AIDS, after progressive multifocal leukoencephalopathy (see above). The organism may be observed as an **intracytoplasmic, cyst-like structure** containing a tiny form of a parasite known as **bradyzoites** or as **crescent-shaped tachyzoites (nucleated form of the parasite)** (Fig. 42-4).

Cajulis et al (1997) pointed out that the **inflammatory component** in smears in toxoplasmosis of the brain may **mimic malignant lymphoma**.

Other protozoa affecting the brain of AIDS patients, such as ***ameba histolytica***, **trypanosomiasis**, and **paragonimiasis** (caused in the Far East by the parasite *Paragonimus westermani*; see Chap. 19), to our knowledge, have not been reported as yet in cytologic samples.

Helminths (Worms): Cysticercosis

The larvae of the **pork tapeworm, *Taenia solium***, may lodge in the brain and other organs,

such as the skin or muscle, and form **cysts** that can be identified on a CT scan. Silver et al (1996) described a case of cysticercosis **mimicking a malignant glioma**. **Aspiration biopsy** of one of the **brain cysts** may yield **anucleated squames** and sometimes **hooklets from the scolex or the head of the larva**, similar to hooklets observed in echinococcosis (see Chaps. 19 and 38).

P.1528

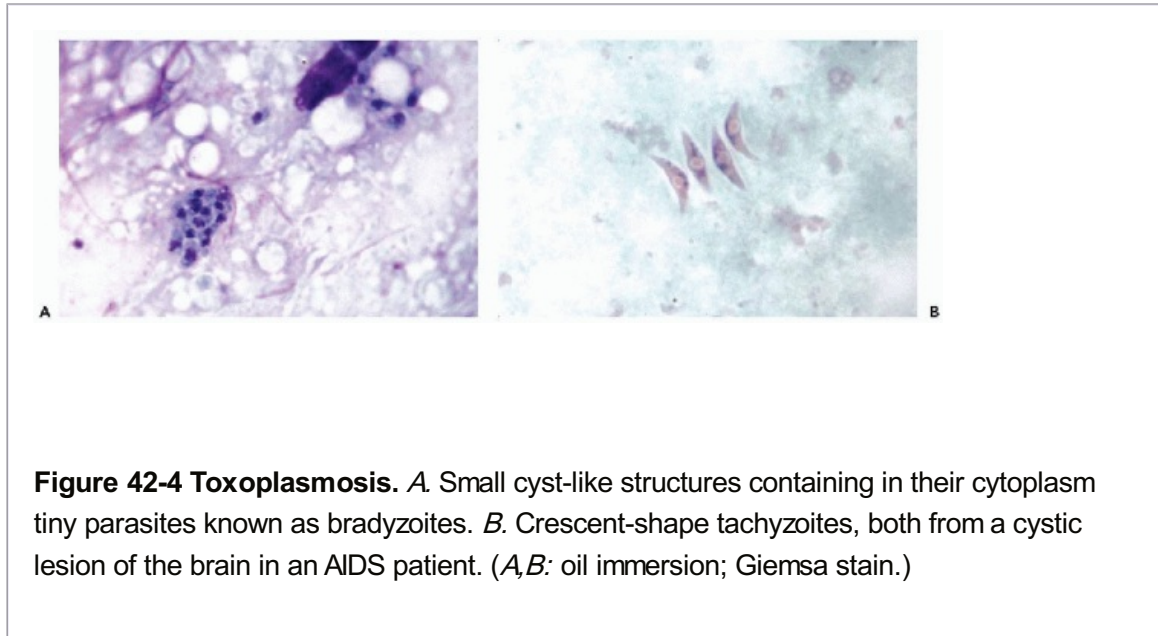

Figure 42-4 Toxoplasmosis. *A.* Small cyst-like structures containing in their cytoplasm tiny parasites known as bradyzoites. *B.* Crescent-shape tachyzoites, both from a cystic lesion of the brain in an AIDS patient. (*A,B*: oil immersion; Giemsa stain.)

However, hooklets may be difficult to recognize if the smear contains a large number of **macrophages**, cell debris and, occasionally, eosinophiles. Kaw (1994) reported a case in which the hooklets were calcified and were **mistaken for psammoma bodies**.

It must be stressed that other processes, such as brain abscesses and sometimes neoplastic processes, may also form cysts that usually can be differentiated from echinococcosis by aspiration cytology.

PRIMARY TUMORS OF THE BRAIN

Tumors located within the **cranial cavity** and colloquially referred to as “**tumors of the brain**,” represent a broad spectrum of lesions, some derived from cell components of the brain and others originating in adjacent organs, such as the meninges, nasal cavity, nerves, and even the inner ear (Liwnicz et al, 1992; DeAngelis, 2001). Further, many of these tumors have divergent natural history and prognosis; therefore, their precise recognition and classification is important from a therapeutic standpoint and prognostic value. Clearly, only experts in neuropathology are capable of precise classification of many of the uncommon brain tumors; however, practicing pathologists and cytopathologists may be called upon to identify some of them in the course of their practice. The technical aspects of tumor localization and smear preparation technique during intraoperative consultations were discussed in the opening pages of this chapter. In this narrative, the cytologic presentation and basic clinical data of the most common and most important neoplasms occurring within the cranial cavity will be discussed (Table 42-2).

Knowledge of patient's age, clinical history, his or her immune status, and radiologic findings, are essential prerequisites for an accurate and differential diagnosis that may include inflammatory lesions (Waldron and Tihan, 2003).

Astrocytic Tumors

Histology

Astrocytomas are the most common primary tumors of the CNS, which range in configuration, hence, in grade, from **low-grade, well-differentiated tumors (tumors grade I)**, to **highly malignant, poorly differentiated high-grade tumors (tumors grade IV)**, the latter also known as a **glioblastoma multiforme**. These tumors may be **diffuse**, that is, without specific borders, or **localized**, at least on radiologic and gross examination. Occasionally, these tumors are **cystic**, particularly in the cerebellum. There are several additional subtypes of the astrocytic tumors, such as **fibrillary**, **pilocytic**, so named because of hair-like appearance of their processes (from Latin, *pilus* = hair), and **gemistocytic** (from Greek, *gemistos* = full or swollen, reflecting the large body of the cell). Still less common variants include **subependymal giant-cell astrocytoma**, a tumor occurring mainly in young patients with a congenital genetic abnormality known as **tuberous sclerosis** (see below).

Low-grade astrocytomas are composed of criss-crossing, loosely structured bundles of relatively **uniform spindly tumor cells with pale, uniform nuclei against a background of fibrillary substance**. The cytoplasm of the tumor cells may display processes (Fig. 42-5C). **Gemistocytic tumors** are characterized by large cells with hugely distended eosinophilic cytoplasm filled with glial fibers, and peripheral **single or multiple nuclei** (Fig. 42-6C).

As the tumors progress in grade, the cells are more densely packed and display **nuclear abnormalities** such as variability in nuclear sizes and hyperchromasia. The apogee of the nuclear and cellular abnormalities is seen in **astrocytoma grade IV or glioblastoma multiforme**, which is characterized by considerable **necrosis, palisading of clearly malignant tumor cells, mitotic activity, and formation of tumor giant cells** (Fig. 42-7C). In smears, the cellularity and the **level of nuclear abnormalities determine the grade of the tumors**.

With the exception of subependymomas and subependymal giant-cell astrocytomas, which are slowly growing tumors that require treatment only if obstructing the flow of CSF, and an occasional **astrocytoma of low grade, confined to the cerebellum, the prognosis of astrocytomas**, whether low or high grade and regardless of the mode of treatment, **is dismal** and the difference in grade merely indicates the duration of tumor progression to death, which is longer in low-grade tumors (DeAngelis, 2001).

P.1529

TABLE 42-2 A SIMPLIFIED CLASSIFICATION OF CENTRAL NERVOUS SYSTEM TUMORS

	Location of Tumor and Prevalence in Population	Subtype	Grade
Astrocytoma	Cerebrum and cerebellum	Protoplasmic	I-II
	Any age: pilocytic astrocytoma usually 1st and 2nd decades	Fibrillary	I-II
		Gemistocytic	II

		Pilocytic	I
		Subependymal giant cell	I
		Malignant (anaplastic)	III
Glioblastoma multiforme	Cerebral hemispheres, stem, cord 45-55 age group		IV
Oligodendroglioma	More common in men		
	Mostly frontal/parietal	Typical	II
	40-55 age group	Malignant (anaplastic)	III
Ependymoma	Ventricles (particularly the fourth), spinal cord, cerebrum	Myxopapillary (sacral)	II
		Malignant	I-II
	Children and adults		III-IV
Choroid plexus papilloma	Fourth ventricle and lateral ventricles		I
Choroid plexus carcinoma	First decade up to adult		III-IV
Medulloblastoma	Cerebellum		IV
	First decade common, young adults rare		
Pineal cell tumors	At site of pineal		I-IV
	Rare at any age		
Neurofibroma	Cranial nerve root; in association with von Recklinghausen's neurofibromatosis		I

Schwannoma (neurilemmoma)	Intraspinal and intracranial (acoustic neuroma)		I
	Adults		
Meningioma	Intracranial and intraspinal; more common in females (4:1)	Various	I
		Malignant	III
	Peak incidence 45		
Melanoma (primary)	Rare at any age		IV
Lymphomas	Cerebrum (any site); meninges and nerve roots	Primary, "microglioma," "reticulum cell sarcoma"	III-IV
	Mostly adults		
Hemangioblastoma	Cerebellum, brain stem, cord		I
	Adults 25-45; male preponderance		
Angioma (+ malformations)	Any site		
	Any age		
Germinoma/teratoma	Pineal and suprasellar regions		III-IV
	Age 10-30; male preponderance		
<i>Craniopharyngioma</i>	Suprasellar		I
	Any age but peak 5-25		
Dermoid/epidermoid cyst	Rare at any age		I

Anterior pituitary adenoma	In pituitary fossa, may extend to suprasellar region	I
	Adults	
Chordoma	Base of skull and sacrum	II-III
	Adults	
Cystic adenoid carcinoma	Nasopharynx; sinuses	III
	Adults	

(Modified from Liwnicz B, et al. The central nervous system. *In* Koss LG, Woyke S, Olszewski W (eds). *Aspiration Biopsy. Cytologic Interpretation and Histologic Bases*. New York: Igaku-Shoin, 1984, with permission.)

Cytology

Low-Grade Astrocytomas

These tumors, also known as **fibrillary astrocytoma**, are characterized by a relatively **sparse population of uniform spindly cells with small, clear nuclei**, fairly abundant clear cytoplasm with multiple, relatively short **cytoplasmic processes**, and fibrillary background (see Fig. 42-5A). In the **pilocytic variant**, the cells show long, thin, hair-like cytoplasmic processes (see Fig. 42-5B). These processes are no longer visible in tumor cells in cerebrospinal fluid (Browne et al, 2004).

The **differential diagnosis** of low-grade fibrillary astrocytoma includes **reactive gliosis** (see Fig. 42-2A,B). The presence of **capillary vessels in the smears is suggestive of the presence of a tumor**.

High-Grade Astrocytomas

The **cellularity** of the smears is much **higher** than in low-grade tumors. These tumors are readily recognized as malignant. **In grade II or III astrocytomas, the nuclei are large, of irregular contour, and hyperchromatic**, even though **the fundamental structure of the tumor is similar to low-grade astrocytomas** (see Fig. 42-6). In the **gemistocytic variant**, the cells are large because of the large cytoplasmic area distended with glial fibers. The nuclei are darker, often double and eccentrically located (see Fig. 42-6C).

In astrocytoma grade IV or glioblastoma multiforme, the structure of a classic astrocytoma is no longer visible and the malignant nature of the tumor is beyond doubt, **with many bizarre tumor cells of various sizes, mitoses, and tumor giant cells** (see Fig. 42-7). The precise cytologic classification of the tumor in smears may require support of clinical and imaging data. The **differentiation from the rare and benign subependymal giant-cell astrocytoma or a metastatic malignant tumor** may cause diagnostic problems (see below). We have also seen a diagnostic error based on the presence of numerous, **large atypical macrophages** in a case of a **cerebral infarct**, mimicking a glioma (Fig. 42-8). Glioblastoma multiforme is one of the rare tumors of the CNS capable of distant metastases to other organs.

A rare variant of this tumor is the **gliosarcoma**, a tumor

P.1532

composed of glial and sarcomatous elements (Burger et al, 2002). Parwani et al (2004) described the cytologic presentation of 14 such tumors. A variety of malignant cell types, including tumor giant cells and sheets of spindly cells, were reported.

Figure 42-8 Infarct of the brain. The smear shows numerous large macrophages with vacuolated cytoplasm and large, dark nuclei, mimicking a malignant tumor.

Subependymal Giant-Cell Astrocytoma

In spite of their ominous appearance, these are rare, **benign tumors**, usually occurring in the lateral ventricles of **young children with tuberous sclerosis**. Tuberous sclerosis is an inherited congenital abnormality of the brain characterized by formation of nodules (tubers) in the cerebral cortex, associated with mental retardation and seizures. **Sebaceous adenomas of the skin** and **angiomyolipomas of the kidney** may be associated with this disease.

Subependymal giant-cell astrocytomas are **tumor-like deposits of bizarre astrocytes** that grow slowly and may undergo calcification. These tumors do not require surgical treatment unless they interfere with cerebral functions. The diagnosis is usually established on clinical and radiologic evidence. The cytology and the differential diagnosis of three such tumors were described by Altermatt and Scheithauer (1992). The tumor **cells were described as eosinophilic with eccentric, often double nuclei with prominent nucleoli**. In a case seen by us, the features of the tumor cells were similar (Fig. 42-9A,B). **The history of tuberous sclerosis and evidence for subependymal location on imaging are essential in the correct recognition of the tumor.**

Figure 42-9 Subependymal giant-cell astrocytoma and oligodendroglioma. *A.* Very large astrocytes with eosinophilic cytoplasm and dark peripheral nuclei are characteristic of subependymal giant cell astrocytoma. *B.* Tissue section corresponding to *A.* *C.* Sheets of monotonous, small cells with scanty clear cytoplasm surrounding the nucleus, with a halo-like effect, characteristic of oligodendroglioma. *D.* Histologic section of the corresponding tumor.

Oligodendrogliomas

These tumors are derived from small glial cells with short cytoplasmic processes and may be **benign or malignant**. Their correct recognition is of clinical value because such tumors have a slow clinical course and appear to **respond better than other gliomas to some forms of chemotherapy** (DeAngelis, 2001). **The benign variant** in smears shows **sheets of monotonous small cells with scanty clear cytoplasm, surrounding the nucleus with a halo-like effect, and fibrillary background** (Fig. 42-9C,D). Focal **calcifications and capillaries** may be seen. **The malignant variant** is characterized by **nuclear abnormalities** in the form of **enlargement and hyperchromasia and evidence of mitotic activity** (Liwnicz et al, 1992).

Mixed Gliomas

Virtually any combination of grades and cytologic features may occur in astrocytomas. This renders their precise classification in cytologic preparations extremely difficult, if not impossible. Gaudin et al (1997) circumvented this problem

P.1533

by **nuclear grading**, which correlated well with survival in 74 patients.

Ependymomas

Histology

These tumors, derived from the ependymal lining of the cerebral ventricles, occur mainly in the fourth ventricle and, thus, cause early hydrocephalus. The tumors may be **benign or**

malignant and may occur in children and adolescents (Helseth et al, 2001). Histologically, the tumors are characterized by **perivascular arrangement of large, uniform columnar cells or pseudorosettes** (Fig. 42-10C) and occasionally formation of true rosettes. In the malignant variant, these landmark structures can be lost. The **nuclei** of the cells of the benign variant are **spherical or oval**, sometimes provided with **nucleoli**, whereas in the **malignant variant**, **obvious nuclear hyperchromasia and abnormalities of the nuclear size and contour** are the rule.

Cytology

In smears, the tumor cells are of **columnar or cuboidal configuration**, often arranged in approximately **circular arrangement (rosettes)** (Fig. 42-10A,B). In the absence of rosettes, the presence of fairly **cohesive sheets of uniform columnar cells** in smears may permit recognition of the tumor. In the benign variant, the nuclei are oval and uniform. Kumar (1997) observed the presence of **nuclear grooves** in 15 of 21 cases of these tumors.

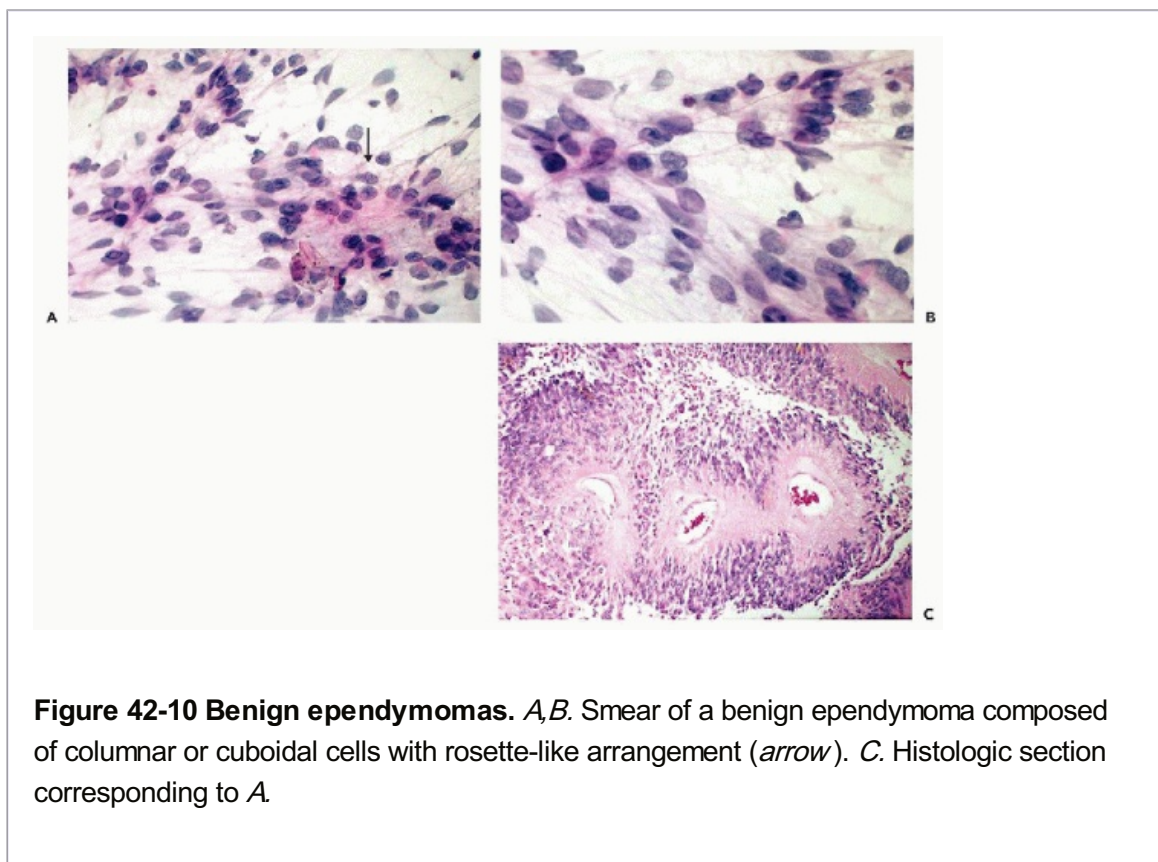

Figure 42-10 Benign ependymomas. *A,B.* Smear of a benign ependymoma composed of columnar or cuboidal cells with rosette-like arrangement (*arrow*). *C.* Histologic section corresponding to *A*.

The **malignant variant** of ependymoma is characterized by **less cohesive clusters** of columnar or cuboidal epithelial cancer cells with **abnormal, hyperchromatic nuclei** (Fig. 42-11). The main point of differential diagnosis in such tumors is **metastatic carcinoma** which, however, usually has a different clinical and radiologic presentation.

Myxopapillary Ependymomas

These tumors **do not occur in the brain** but in the terminal portion of the spinal cord, the so-called **filum terminale**, or rarely **within the dura of young patients**. The **histology and cytology** of the tumor are very similar. The tumors are composed of **fern-like structures and rosettes**, formed by large, columnar tumor cells with opaque cytoplasm, surrounded by myxoma-like stroma. The stroma and homogeneous material found in the center of rosettes are

periodic acid-Schiff (PAS) and mucicarmine positive. The tumors are capable of recurrence and metastases.

Initially, most reported cases of cytologic diagnosis of these tumors were in metastatic foci (Woyke and Czerniak, 1978; Koss et al, 1992). Primary tumor diagnoses were reported by Ng et al (1998), Pohar-Marinek and Frkovic-Grazio (1998) and Ortega et al (2002). The recognition of the tumor is based on identifying **the fern-like structures and rosettes lined by columnar tumor cells**. A rich network of capillaries may be observed (Fig. 42-12). Homogeneous stromal globules of unknown significance were observed in some cases (Ortega et al, 2002).

P.1534

Figure 42-11 Malignant ependymoma. *A.* Large cells with enlarged hyperchromatic nuclei with irregular contour. *B.* Tissue section of the corresponding tumor.

Unusual variants of this tumor were described in the literature. Gelabert-Gonzalez et al (2001) described a case of two synchronous tumors in a girl age 15. Fournay et al (2004) described a tumor with pleomorphic giant cells. Rao et al (2002) described such a tumor in a subcutaneous location. Awaya et al (2003) described a case of a malignant tumor with numerous mitotic figures.

Layfield (2003) reviewed 14 neoplastic lesions involving the sacrum or the perisacral region, diagnosed by aspiration biopsy. Only one was a myxopapillary ependymoma. Ten of the 14 tumors were chordomas, described in Chapter 36. Layfield pointed out that, very rarely, **myxoid chondrosarcomas** or **metastatic tumors of the gastrointestinal tract** should be considered in the differential diagnosis.

Subependymomas

Subependymoma is a rare benign tumor, usually located under the ependyma of the lateral or fourth ventricles and composed of clusters of small cells of astrocytic or ependymal origin, embedded in a fibrillar matrix (Scheinker et al, 1945). Some of these tumors may have large, pleomorphic nuclei (Burger and Scheithauer, 1994). Cytology of these tumors was reported in crush preparations by Inayama et al (2001) and by Raisanen et al (2003). The tumors are characterized by cells with small, elongated nuclei and cytoplasm forming long intersecting processes. Variability in sizes and shapes of nuclei was observed in the case reported by Raisanen et al (2003).

Choroid Plexus Tumors

These very rare tumors may be benign or malignant. The **benign variant**, also known as **choroid plexus adenoma**, shows **orderly papillary cluster of cells with small nuclei** similar to normal choroid plexus (Koss et al, 1992) (see Fig. 42-2D). Such a case, with the diagnosis established on aspirated ventricular fluid, was described by Buchino and Mason (1992) and in touch preparations by Liwnicz et al (1992) and Pai et al (2001).

The **malignant variant** usually occurs in **the lateral ventricles in infants and in the fourth ventricle in adults and carries a dismal prognosis**. Some of these tumors may be **pigmented** (Boesel and Suban, 1979). Several cases of cytologic diagnosis of these tumors were described in cerebrospinal fluid (Kline, 1962; Bigner and Johnston, 1983; Rosenthal, 1984), or in direct aspirates of the **cystic tumor** (Kim et al, 1992). Kim et al described **papillary clusters of malignant cells and single cancer cells with lobulated nuclei**, the latter feature not having been described before. In **infants**, the cytologic diagnosis can be established with reasonable assurance in the correct clinical setting but, in adults, it is virtually impossible to differentiate cells from a malignant choroid plexus tumor from a metastatic adenocarcinoma, in the absence of **clinical and imaging data**.

Medulloblastoma

Histology and Natural History

This highly malignant tumor occurs mainly in children and less often in young adults. The tumor, occurring in the **cerebellum**, is the only malignant tumor of the CNS **consistently capable of spread to the spinal canal and of systemic metastases**. The tumor is considered to be a member of the group of “**small, blue cell tumors**” of childhood and is composed of sheets of small-to-medium size malignant cells with scanty cytoplasm that **mold** with each other, and often form **rosettes**, arranged around central neurofibrils (Homer-Wright rosettes) or **pseudorosettes**, when arranged around blood vessels. The tumors are most likely derived from primitive cells that can differentiate into neurons. The tumors resemble **neuroblastomas**, occurring primarily in the adrenal medulla and **retinoblastomas**, occurring in the eye (see Chaps. 40 and 41). **Primary neuroblastomas** of the brain may occasionally occur and can be recognized by the presence of fine **neurofilaments** in the center of the rosettes.

Cytology

The cytologic presentation of medulloblastoma in cerebrospinal fluid was discussed and illustrated in Chapter 27. The smears of **direct aspirates** of the tumor are **cellular and composed of small- to medium-sized cells** with relatively large, **hyperchromatic nuclei** and scanty cytoplasm. **Nucleoli** are not prominent. Arrangement of cells in **long files**,

P.1535

with some level of **molding** of adjacent cells, is not uncommon and is reminiscent of similar cell arrangements in small-cell carcinoma of the lung and mammary carcinoma (see Chaps. 20 and 29). **Rosette formation** is common (Fig. 42-13). The differential diagnosis of this tumor includes morphologically similar tumors, such as **neuroblastoma**, which is usually metastatic but may be primary in the brain (see Fig. 27-15C) and **the exceedingly rare metastatic retinoblastoma** (see Fig. 27-15D).

Figure 42-12 Myxopapillary ependymoma metastatic to the skin. *A-D.* Aspiration smear. *A* Elongated columnar cells arranged in rosette-like structure. *B.* Center of the rosette was filled with mucicarmine-positive material (mucicarmine staining). *C.* Large cluster of cells arranged in fern-like pattern. *D.* Slim cylindrical cells with long cytoplasmic processes arranged in palisade-like structures. *E.* Tissue section of the subcutaneous nodule with myxopapillary structures. *F.* Higher magnification of one of the papillae showing myxomatous stroma surrounded by slim columnar cells. (From Woyke S, Czerniak B. Fine needle aspiration cytology of metastatic myxopapillary ependymoma. *Acta Cytol* 22:312-315, 1978.)

Midline Tumors

This large group of tumors, of diverse origin and histologic presentation, occupy the area surrounding the cerebral midline (diencephalon). This term covers a variety of tumors occurring in **the pineal, the pituitary, and the base of the skull (craniopharyngioma)**. The tumors are generally accessible to aspiration biopsy.

Tumors of the Pineal Region

The tumors of the pineal region are **benign or malignant pinealomas, benign dermoid cysts, malignant teratomas, and germinomas**. Malignant **pineoblastomas** are composed of small cells, similar to cells of medulloblastoma and related tumors.

Germinomas are highly malignant tumors that occur predominantly in **adolescent boys**. It is **not known whether the germinomas are of pineal origin** but they are usually observed in this region. Most germinomas are

P.1536

similar to **testicular seminomas or ovarian dysgerminomas**, and are composed of sheets of epithelial cells with a lymphoid infiltrate. Some tumors may also show features of **embryonal carcinoma**. As is also the case in testicular tumors, isolated **multinucleated giant cells, positive for human chorionic gonadotropin**, and thus resembling placental **trophoblasts**, may occur in germinomas.

Figure 42-13 Medulloblastoma in a child. *A.* Sheet of small tumor cells with scanty cytoplasm and nuclei of similar sizes. Nuclear flattening on “molding” is visible at the bottom of the cluster. *B.* Similar cells forming a Homer-Wright rosette around a central lumen filled with neurofibrils (not visible in this photograph). *C.* Biopsy of the cerebellar tumor, morphologically similar to other “small blue cell tumors” of childhood. Rosette formation may be noted.

Cytology

A case of **pineoblastoma** was illustrated by Liwnicz et al (1992) as composed of **dispersed small cancer cells**, similar to cells of medulloblastoma. The cytologic features of **germinomas** in smears resembles that of a seminoma, in which fairly **large cancer cells with prominent nuclei and nucleoli** appear in company of **lymphocytes**. The elevation of the beta subunit of **human chorionic gonadotropin** in the spinal fluid, in the presence of metastatic seminoma, was recorded (Gindhart and Tskahara, 1979). Ng (1995) described

aspiration smear cytology of five germinomas and, besides the customary mixture of large cancer cells and lymphocytes, recorded the presence of **amorphous, eosinophilic material in the background of air-dried smears**, somewhat similar to the background "tiger" that may be observed in seminomas (see Chap. 33).

Pituitary Gland

Brief Synopsis of Histology and Cytology

The pituitary gland is composed of three parts: anterior or adenohypophysis, intermediate zone, and posterior or neurohypophysis. Normal anterior part of the pituitary is composed of nests of cells that are **eosinophilic, basophilic, or chromophobes** according to the staining qualities of their cytoplasm. These cells produce a variety of hormones ranging from growth hormone to ovary-stimulating hormones.

The anterior part is the principal site of **hormone-producing tumors** that are, for the most part, benign (**pituitary adenomas**) but may be malignant (**pituitary carcinomas**). These lesions may be the target of cytopathologic investigations.

The distinction between benign and malignant tumors is arbitrary because both types can destroy the sella turcica and adjacent bony structures of the skull. Metastases derived from pituitary carcinoma are rare (Kovacs and Horvath, 1983). Tumors of the anterior pituitary are solid or cystic, may be nonfunctional (about 30%), or secrete a broad variety of hormones, in keeping with the role of the anterior pituitary as the regulatory center of endocrine functions of the body. Of interest in the context of this book is oversecretion of **prolactin** that may lead to **amenorrhea** (see Chap. 8), **growth hormone** leading to **acromegaly** and **adrenocortropin (ACTH)**, and leading to **Cushing's syndrome**. All these syndromes have been mentioned or discussed elsewhere in this book. The correlation of the endocrine activity with the specific cell type is poor with most adenomas composed predominantly of **chromophobe cells**, but acidophilic or basophilic cell components may be present or even dominant. The clinical diagnosis of a pituitary tumor is usually rendered on clinical and endocrine grounds. The

P.1537

precise classification of these tumors is based on immunohistologic analysis of cell types and their function.

Abnormalities of the posterior lobe of the pituitary gland are very rare, may lead to **diabetes insipidus**, and are not the target of cytologic investigation.

Cytology

The pituitary gland is virtually never aspirated; therefore, the knowledge of cytology of pituitary adenomas and carcinomas is based on touch preparations. **Immunostaining for various hormones** is essential to correlate morphology with function.

In **adenomas** of the anterior pituitary, the epithelial tumor cells form **cohesive sheets**, often displaying **basophilic or eosinophilic cytoplasmic staining** in Papanicolaou stain, in keeping with the fundamental structure of the normal organ (Fig. 42-14). Formation of acini or of papillary structures may occur (Ng, 1998). Kontogeorgos et al (1995) analyzed in some detail the principal features of pituitary adenomas. The **growth hormone-producing tumors** were characterized by **nuclear pleomorphism, multinucleation, and fibrous bodies**. **Prolactin-producing tumors** were characterized by **small-cell and nuclear size** and the presence of **microcalcifications**. In the **corticotrophic (ACTH secreting) adenomas**, there was an

accumulation of **hyaline material in the cytoplasm** of tumor cells. Pegolo et al (1995) reported that **nuclear pleomorphism** and **higher proliferation index** were more likely to occur in smears and touch preparations of **functioning pituitary adenomas**, secreting growth hormone, prolactin, or ACTH, than in nonfunctioning adenomas.

Craniopharyngioma

Craniopharyngiomas are uncommon tumors located in the **upper reaches of the nasal passages and the base of the skull**. The tumors may be **solid** or **cystic** and may expand to compress parts of the brain. The tumors resemble the structure of the enamel organ of teeth and are composed of **nests and cords of squamous epithelium nested in loose fibrous stroma**.

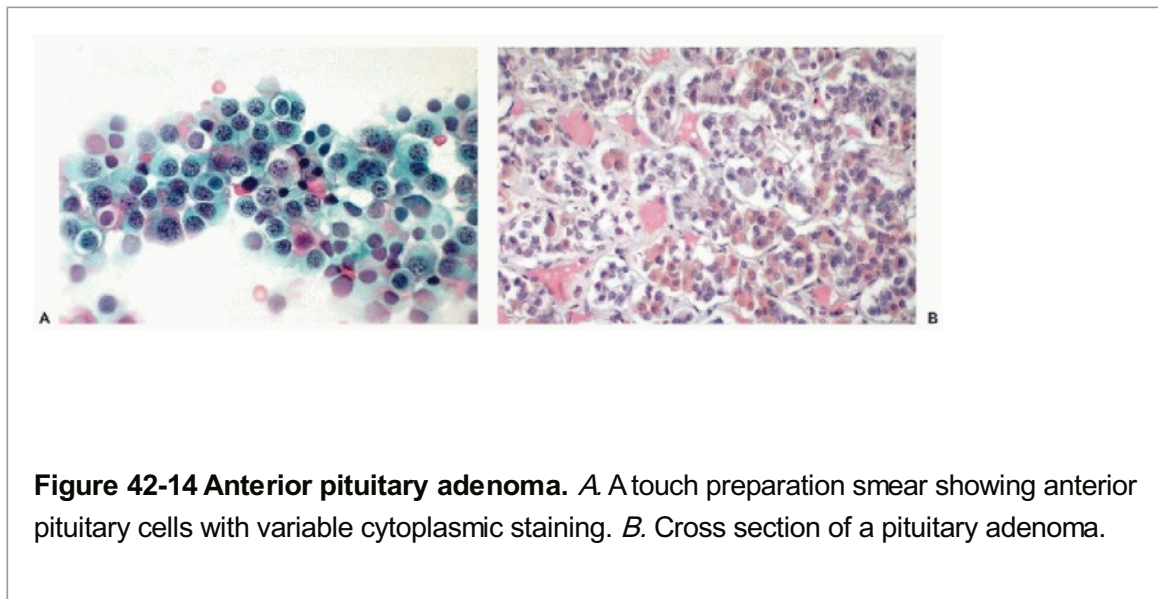

Figure 42-14 Anterior pituitary adenoma. *A.* A touch preparation smear showing anterior pituitary cells with variable cytoplasmic staining. *B.* Cross section of a pituitary adenoma.

These tumors are very rarely aspirated, except for the **cystic form** that may present a problem of differential diagnosis with a cystic anterior pituitary adenoma.

The **cytology** of craniopharyngioma is that of clusters or sheets of differentiated squamous cells, often against the background of keratin debris and cholesterol crystals (Fig. 42-15). Similar features were reported by Mincione et al (1991) and by Smith et al (1999).

Intracranial Cysts

Besides the cystic form of craniopharyngioma, many primary or metastatic brain tumors and cysts caused by **cysticercosis** (see above) and primary cystic lesions may be observed within the brain and adjacent organs. The cysts may be derived from the **ependyma**, **arachnoid**, **pineal gland**, from a nasal vestigial organ known as **Rathke's pouch**, or **meninges** (Koss et al, 1992).

There is very limited cytologic experience with primary cysts of the brain. We have observed an **arachnoid cyst** that yielded sheets of benign epithelial cells (Fig. 42-16) and a **cholesteatoma**, most likely derived from the upper nasal passages. The latter lesion was lined by squamous epithelium and the cytologic preparation contained clusters of small squamous cells against a background of debris (Fig. 42-17). Pinto (1996) observed elevated levels of **carcinoembryonic antigen** in cystic brain lesions, mainly in **metastases from lung and gastrointestinal tract**.

Another exceptionally rare tumor that may be partially cystic is the **endolymphatic sac tumor**,

arising in the endolymphatic ducts of the inner ear. Histologically, the tumor has the configuration of a low-grade papillary adenocarcinoma. It may be a manifestation of the congenital genetic disorder, the **von Hippel-Lindau syndrome**, characterized by vascular tumors of multiple organs such as the eye and the brain (summaries in Wenig and Heffner, 1996; Devaney et al, 2003; Choo et al, 2004). Cytology of the fluid aspirated from such a cystic intracranial lesion disclosed epithelial cell clusters composed of orderly cells with bland nuclei (Murphy et al, 2001).

P.1538

Figure 42-15 Craniopharyngioma. *A.* Tight cluster of spindly cells with eosinophilic cytoplasm surrounded by loose fibrinous stroma. *B.* Histologic section of the corresponding tumor showing squamous epithelium and gland-like structures.

Figure 42-16 Arachnoid cyst. *A.* Small spindly cells, some in palisade-like arrangement, corresponding to the thin-walled cyst shown in *B.*

Figure 42-17 Cholesteatoma. *A.* Small cluster of cells with eosinophilic cytoplasm in proteinaceous background. *B.* The lining of the lesion, composed of keratinizing squamous epithelium.

P.1539

Hemangioblastoma

Another tumor that may be associated with von Hippel-Lindau syndrome is hemangioblastoma, a tumor composed of a network of fine **capillary vessels** with nests of large cells with foamy, clear cytoplasm.

Commins and Hinton (1998) reported on the **cytology** of six such tumors and described **cohesive sheets and clusters of large cells** with minimal to moderate nuclear abnormalities and clear foamy cytoplasm. Nuclear grooves were observed in some cells. These authors also discussed the differential diagnosis of these rare tumors, which include metastatic renal carcinoma and, more remotely, meningiomas. Immunocytochemistry may be helpful in debatable cases.

MENINGIOMAS

Histology

These tumors are usually derived from the **dura** or the **arachnoid** and form firm nodules of various sizes. Many of the small tumors are completely asymptomatic and their discovery is incidental. However, **when they grow to substantial sizes**, they may cause various symptoms referable to the CNS. Once the tumors spread along the dura, particularly at the base of the skull, they are difficult to remove and may cause the death of the patient.

Meningiomas can also be observed in the orbit and the nasal cavity and sometimes in the mediastinum (see appropriate chapters).

Figure 42-18 Meningioma. *A,B.* Compact sheets of small epithelial cells, some showing faint intranuclear cytoplasmic inclusions. In *B*, a small whorl may be noted. *C.* A characteristic whorl or a pearl-like arrangement of meningeothelial cells. *D.* Cross section of a meningioma.

These tumors have a number of **histologic patterns**: most are **meningeothelial**, that is, composed of sheets of large epithelial-type cells with clear cytoplasm, often forming whorls; **fibroblastic**, in which the cells form fascicles of elongated cells, **papillary**, and extremely rare variants, such as **secretory** meningioma and **metaplastic** meningioma (containing components of cartilage and fat, etc. Summary in Rosenblum, 1996). There is a significant question whether truly **malignant meningiomas** occur and, if so, whether they have a distinct morphologic pattern. It appears to be the consensus today that any meningioma, if strategically located and difficult or impossible to remove, may kill a patient after many years of slow growth.

Cytology

The aspirates of **benign meningiomas** are characterized by flat **sheets of meningeothelial cells** that resemble epithelial cells **with clear cytoplasm and small, spherical nuclei**. Sometimes the cells are dispersed and there may be some variability in nuclear sizes. These cells tend to form **whorls** in which the cells are arranged in **onion-like fashion**, not unlike squamous pearls, repeatedly discussed elsewhere in this book (see Chaps. 11 and 20). However, the whorls do not show any evidence of keratinization and the cytoplasm of the component cells remains translucent (Fig. 42-18).

P.1540

There are two other features of these tumors that are common: the presence of **intranuclear cytoplasmic inclusions** and **psammoma bodies**. Kobayashi (1993) and Vogelsang et al (1993) attempted to describe cytologic criteria of benign versus malignant meningiomas. As mentioned above, the existence of a truly malignant (metastasizing) meningioma is in doubt and no prognostic conclusions should be drawn from cytologic patterns.

Figure 42-19 Schwannoma. The densely packed cells form palisade-like structures separated by clear space (Verocay bodies, *arrow*).

NERVE SHEATH TUMORS

Tumors of nerve sheaths (**neurilemmomas** or **schwannomas**) may be found in various locations in the skull, the most common and important being the **acoustic schwannoma**, derived from the eighth cranial nerve and often involving the angle between the portion of the middle brain known as the pons and the cerebellum (cerebello-pontine angle). Other tumors of this type may be derived from other cranial nerves as well as peripheral nerves in various locations, as described in other chapters.

The histologic structure of these tumors is characteristic and has been repeatedly described in other chapters. The cells are arranged in **palisades lining hyaline acellular bands (Verocay bodies)**.

Figure 42-20 Malignant lymphoma. *A.* Smear composed of dispersed small lymphoid cells with variable nuclear sizes. Nucleoli may be observed. *B.* Malignant lymphoma in Virchow's space.

The palisading is also reflected in the cytologic preparation and allows a secure diagnosis of these tumors (Fig. 42-19).

MALIGNANT LYMPHOMAS

Non-Hodgkin's lymphomas may be **primary** in the brain, **particularly in patients with AIDS** (Margello et al, 1990), or **metastatic**. The **unique histologic feature** of lymphoma of the brain is the accumulation of malignant lymphocytes in **perivascular spaces** (Virchow-Robin spaces). The cytologic presentation of malignant lymphomas of the brain is very similar to that of other organs (Fig. 42-20) and need not be repeated here (see Chap. 31). It is of interest that in some primary lymphomas of the brain, one may observe **multinucleated giant cells** and **macrophages** containing particles of HIV virus in **electron microscopy** (Mizusawa et al, 1987). Another feature that is characteristic of primary malignant lymphomas in patients with AIDS is the presence of **Epstein-Barr virus**. Yu et al (1996) were able to identify this virus in smears by **in situ hybridization** in 19 of 23 cases, 12 of whom had immunoblastic and 11 large B-cell lymphomas.

We have seen an example of **granulocytic sarcoma**, a form of chronic myelogenous leukemia, of the brain with numerous immature eosinophiles and Charcot-Leyden crystals (Fig. 42-21A). A similar case was described in Chapter 27.

Multiple myeloma may also involve the brain, usually by extension of skull lesions. The **plasma cells** are readily recognized in smears (Fig. 42-21B).

METASTATIC TUMORS

Metastatic tumors from all body sites may be observed in the brain and sometimes may be the **first manifestation of**

P.1541

an occult primary tumor. Repeatedly, we have observed that such metastases, particularly if single, may be mistaken clinically and radiologically for primary tumors, such as glioblastoma multiforme. In fact, in some cases, the differential diagnosis between a metastasis and glioblastoma may be difficult (Koss et al, 1992).

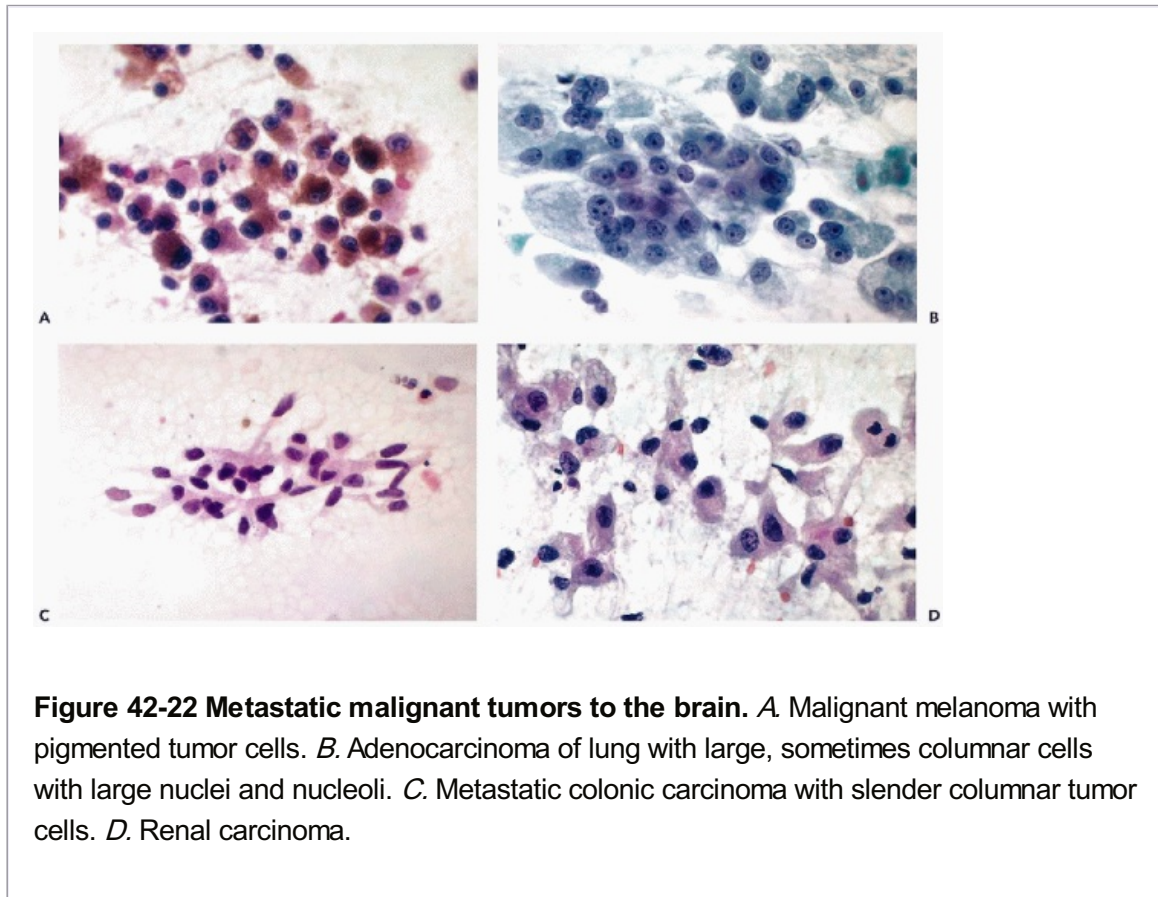

Figure 42-21 Chloroma and multiple myeloma. *A.* A Giemsa-stained aspiration smear of a chloroma involving the central nervous system. The variability of granulocyte-precursor cells is well documented. *B.* Multiple myeloma, bone of skull. The smear is composed of numerous plasma cells. (*A*, highpower.)

Among the important sources of metastases, **malignant melanoma** may form brain metastases, sometimes **many years after the removal of an inconspicuous primary tumor**, that may have been misdiagnosed as a nevus. **Bronchogenic carcinoma, mammary carcinoma, colonic carcinoma, and renal carcinoma** are among the most common metastatic tumors. However, **any** malignant tumor may form brain metastases. We have seen examples of metastatic

P.1542

tumors of the **thyroid, prostate**, and in a young woman, of **choriocarcinoma**.

Occasionally, it is possible to recognize the primary origin of the metastasis in aspirated samples. Thus, **melanin pigment** identifies a **metastatic melanoma** (Fig. 42-22A); the large, **columnar cells mimicking normal bronchial cells**, suggest a bronchogenic adenocarcinoma (Fig. 42-22B); **slender columnar cancer cells** suggest a colonic cancer (Fig. 42-22C); cancer cells with **abundant pale eosinophilic cytoplasm** may suggest **renal carcinoma** (Fig. 42-22D). Other features that may be helpful are **psammoma bodies**, suggestive of ovarian or thyroid origin, and **large tumor giant cells**, aspirated from the brain of a **woman in the reproductive age group**, suggesting a **choriocarcinoma**.

Many other diagnostic clues were discussed in chapters related to the cytology of individual tumors.

PARANEOPLASTIC SYNDROMES

Of special interest is the occurrence of **paraneoplastic syndromes** in patients with malignant tumors (summary in Darnell and Posner, 2003). **Canexia, hypercalcemia, and Cushing's syndrome** are the most common manifestations of these disorders which are attributed to the secretion of specific immunoglobulins, expressed in neurons, by the primary or metastatic

tumors. The reason for mentioning this entity within the context of this chapter is the frequent occurrence of the syndromes as the **first manifestation of cancer**, which is most often an oat cell carcinoma of lung but may also occur with cancers of the breast, colon, ovary, or lymphomas (Rosenblum, 1996). The cytopathologist may play a key role in the identification of the primary or metastatic tumors.

Acknowledgments

We thank Dr. Josefina Llena, Associate Professor of Pathology (Neuropathology) and Attending Neuropathologist at Montefiore Medical Center for her expert assistance in writing and illustrating this chapter.

HISTORICAL OVERVIEW

There is no doubt that cancer cells from almost any kind of malignant tumor can, and often do, enter into the blood stream and are, thereby, transported to distant organs where they may lodge and form metastases (Batson, 1940). Death from cancer in these patients is the result of metastatic dissemination. Visceral metastases were long known to be more common and patients' survival shortened when venous invasion by malignant tumors was demonstrated (Brown and Warren, 1938; Sunderland, 1949; Grinnell, 1950; Collier et al, 1958; Friedell and Parsons, 1962). Goldmann (1906) reported grossly visible venous invasion by tumor in about 20% of 500 necropsies and microscopic invasion of veins in nearly 10% more (Fig. 43-1). Key references to the original 19th and early 20th century concepts of tumor cell embolization as a mechanism for dissemination of cancer may be found in historical reviews by Ewing (1940), Willis (1952), Coman (1953), West et al (1964), Griffiths and Salsbury (1963), and Watne et al (1966).

The number of cancer cells within the blood stream (excluding leukemias) is infinitesimal when compared with the number of normal blood cells. Thus, it is extraordinary to find cancer cells in routine blood smears, though such cases have been reported, as the so-called “**carcinocythemia**” (Finkel and Tishkoff, 1960; Goodall et al, 1961; Rappaport, 1966; Carey et al, 1976; Myerowitz et al, 1977; Dannaher et al, 1979; Ejheckam et al, 1979; Krause, 1979; Solanki et al, 1980; Gallivan and Lokich, 1984; Irie et al, 1985; Yam and Janckila, 1987; Lugassy et al, 1990; Maldonado et al, 1991; Sile et al, 1999; Rodriguez-Salas et al, 2000).

A systematic search for cancer cells in the circulating blood of cancer patients became a major research target in the 1950s and 1960s, as a possibly valuable predictor of disease progression and guide to therapy. The task of separating or concentrating these cells and giving them their proper identification proved to be a major technical problem, and interest in the research community waned over the next few years.

During the 1990s, technical advances in immunocyto-chemistry and molecular biology reignited interest in the identification of circulating cancer cells in peripheral blood.

P.1545

In this chapter, we summarize earlier efforts and report on the current status of these investigations.

Figure 43-1 Venous invasion by cancer is common, and occasionally there is massive intravascular growth. A testicular teratoma is illustrated here, growing upward within the inferior vena cava. Billroth reported just such a case in 1855 as one of the first examples of venous invasion by cancer. (Cited by Willis RA. *The Spread of Tumors in the Human Body*. St. Louis: C. V. Mosby, 1952.)

Older Studies

The earliest recorded description of free-floating cancer cells in a specimen of blood was by Ashworth in 1869. He reported finding pigmented tumor cells in direct smears of postmortem saphenous venous blood from a 38-year-old man who died with disseminated subcutaneous malignant tumors, presumably a malignant melanoma. Isolated observations of a similar nature were subsequently reported by Schleip (1906) and Ward (1913) in cases of gastric carcinoma, by Marcus (1917) in finger blood from a patient with lung cancer, by Loeper and Loeste in two patients with sarcoma (cited by Ewing, 1940), and by Quensel (1921) in the hearts' blood from six of 50 cadavers with various malignant tumors.

In 1934, Pool and Dunlop carried out the first deliberate search for cancer cells in the blood from living patients. Their technique was crude: 5 ml of oxalated blood was hemolyzed with 15% acetic acid and the centrifuged sediment fixed with 10% formalin in alcohol, then embedded in paraffin and step-sectioned. They found "large spherical cells with hyperchromatic nuclei" in 17 of 40 cancer cases, but also in one patient with a benign gastric ulcer.

In 1954, Cole, Packard, and Southwick demonstrated cancer cells in the perfusate from mesenteric vessels of a resected segment of colon with carcinoma. In the following year, Fisher and Turnbull studied 25 consecutive patients with colorectal carcinoma undergoing surgical resection and found tumor cells in the blood and perfusate from mesenteric veins of 8 (32%). They suggested that tumor cells were dislodged by operative manipulation and Turnbull et al (1965) subsequently reported that ligation and division of the lymphovascular pedicle, before manipulation of the tumor, increased 5-year survival.

A study of major importance was the work of Engell in 1955, who reported in great detail on the incidence of cancer cells in regional venous and peripheral blood. He used 2 to 5 ml of heparinized blood in most cases, lysed the red cells with 1% saponin, and embedded the remaining cellular sediment in paraffin. In serial sections stained with hematoxylin and eosin, Engell found **cancer cells in blood draining the tumor area** of 63 of 107 colorectal carcinomas (59%), 6 of 8 cases of gastric carcinoma, 3 of 4 cases of lung cancer, and 3 of 6 cases of breast cancer. Peripheral blood from the cubital vein of 14 patients with advanced, inoperable carcinoma was examined, and cancer cells were found in 7, whereas in 70 patients with operable carcinoma, cancer cells were identified in only 10. Although cancer cells were more common in patients with more anaplastic tumors, there was no demonstrable relationship to the stage or to operative manipulation of the tumor. In a follow-up report 4 years later, Engell (1959) was unable to correlate the presence or absence of cancer cells in the peripheral blood with survival.

P.1546

Engell's work marked the beginning of a period of extraordinary interest in cancer cells in the blood. During little more than a decade after his second report, there were many other publications concerned with the technical problems of preparation and cytologic interpretation, as well as the actual results and their clinical correlation (Pruitt et al, 1958, 1963; Reiss, 1959). Because accuracy of the examination and interpretation of reported results depends on the quality of the preparation, a brief review of the preparatory methods used at that time is necessary.

Early Technical Methods

The great variety of techniques that had been proposed for processing peripheral blood specimens was probably a reflection of dissatisfaction with any one of them. Most widely used were the methods of Seal (1956, 1959, 1964), Roberts et al (1958), Long et al (1959), and Malmgren et al (1958). Their common purpose was the selection or concentration of any cancer cells that might be present in the blood. All of the methods involved removing the red blood cells and as many normal leukocytes as possible, while retaining cancer cell morphology and quantitative reproducibility.

Separation of the red cell mass was accomplished either by **hemolysis**, initially **with water** (Quensel, 1921), and later **with acetic acid** (Pool and Dunlop, 1934; Fisher and Fisher, 1959; Romsdahl et al, 1965), or by **saponin** (Engell, 1955; Nedelkoff et al, 1961; Ericksson, 1962).

Enzymes, such as streptolysin-O, were used by Potter and Malmgren (1958). **Sedimentation**, usually with an accelerating factor such as **fibrinogen** (Buckley et al, 1950; Sandberg and Moore, 1957; Roberts et al, 1958), **dextran** (Alexander and Spriggs, 1960; deCarvalho, 1960; de Mello, 1963), **phytohemagglutinin** (Li and Osgood, 1949) or **hemolymph heteroagglutinin** (Watne et al, 1966), were also tried.

Separation of cell types may be facilitated by **differential sedimentation or centrifugation** after suspending the blood in a solution of albumen (Fawcett et al, 1950; McGrew, 1954; Roberts et al, 1958), gum acacia (Spear, 1948), or silicone of specific gravity adjusted between that of the heavier red blood cells (1.092-1.097) and the lighter cancer cells and lymphocytes (1.056-1.065) (Seal, 1959). **Polyvinylpyrrolidone (PVP)** and a detergent "wetting" agent were often added to prevent cell clumping and to keep platelets and cellular debris in suspension during centrifugation. Danielsson (1961) suggested using a spiral centrifuge for separation of the lighter cellular elements, but this offered little practical advantage for the relatively small

volumes of blood usually examined. Polymorphonuclear leukocytes, which are heavier than lymphocytes and most cancer cells, were removed by differential centrifugation, or they were differentially lysed by **streptolysin-O**. None of these methods worked perfectly.

Figure 43-2 Cells of carcinoma of the breast in peripheral blood. *A*. Group of cancer cells isolated from the antecubital vein during skin preparation prior to surgery. L, lymphocyte (arrow). Prepared by fibrinogen sedimentation, differential centrifugation over albumen and smearing directly on a glass slide. *B*. Direct smear of resected tumor from the same patient. (*A,B*: Oil immersion.) (Courtesy of Dr. E. McGrew, University of Illinois. From Cole WH, et al. The dissemination of cancer cells. Bull NY Acad Med 34:163-183, 1958.)

A technique for **removing phagocytic leukocytes** was introduced by Kuper et al (1961), who **incubated the heparinized blood with carbonyl iron of approximately 3 μ m particle size**, and then removed the iron-containing cells by stirring the solution with a **magnet**. Buckman et al (1984) later introduced **immuno-rosetting** to select breast cancer cells. These methods were revisited in recent years (see below).

After processing the blood by any one, or several, of these methods, the final cell suspension was transferred to membrane filters (Seal, 1956) or centrifuged onto glass slides (Erickson, 1962), or simply smeared on glass slides and stained. Membrane filters were more convenient and more popular and had the advantage of possibly better quantitation (Fig. 43-3). Much better cell detail was obtained by any of these cytologic methods than by stepsections of the cell sediment after paraffin embedding. The choice of stain was a matter of personal preference. Hematoxylin and eosin or the Papanicolaou stain was commonly used with all types of preparations; Wright-Giemsa or other hematologic stains, and the metachromatic fluorochrome acridine orange (de Mello, 1963) were generally restricted to smears on glass slides.

Best cell morphology was obtained by Roberts et al (1958,

P.1547

1961) using fibrinogen sedimentation to remove red blood cells, then concentrating any cancer cells in the supernatant plasma by centrifuging over an albumen solution of specific gravity 1.065. Most cancer cells collect and can be aspirated from the plasma-albumen interface,

washed, streaked directly on glass slides, and stained with the Papanicolaou method (Fig. 43-2).

Figure 43-3 A,B. Clumps of cancer cells in venous blood of patients with bronchogenic carcinoma. Specimens on Millipore filters prepared by silicone flotation method of Seal. (Courtesy of Dr. S. H. Seal.)

Direct **separation of cells by size** alone was undertaken using either a 10- μ m pore membrane filter (West et al, 1964) or a 4.5- to 5- μ m pore perforated plastic membrane sieve (Seal, 1964). The latter method gave technically good preparations, in addition to its great simplicity. A sample of anticoagulated blood was simply poured through the perforated plastic membrane, which retained the larger cells, including cancer cells. The membrane itself remained clear and transparent during staining and could be mounted on a glass slide.

Initial Observations

Recognition of Malignant Versus Benign Cells in Blood

Because of methods used to process the blood, cellular morphology was often suboptimal and poorly preserved cancer cells were difficult or impossible to distinguish from large immature hematopoietic cells. In some impeccable preparations, conventional criteria for recognition of epithelial cancer cells did apply, but this was only rarely the case. Consequently, **the major source of discrepancies in reported results was due to differences in interpretation and classification of certain cells that are uncommonly found in ordinary blood smears** (Ederer et al, 1965). Criteria for the differential diagnosis of cells likely to be confused with cancer cells in blood, have been described in detail by Sandberg et al (1959), Alexander and Spriggs (1960), McGrew and associates (1960, 1962, 1965), Scheinin and Koivuniemi (1962), Griffiths (1965), and the Circulating Cancer Cell Cooperative (Nadel and Goldblatt, 1965).

Megakaryocytes, endothelial cells, and immature hematopoietic cells that are rare in peripheral blood smears from individuals without hematologic disorders, are found with surprising regularity in the concentrates prepared for cancer cell studies.

Megakaryocytes

There are major differences in the morphology of megakaryocytes before and after passage through the lungs. In prepulmonic blood taken from azygos vein or vena cava draining the

marrow rich ribs, vertebrae, or pelvis, megakaryocytes are relatively numerous and very large, spherical or oval, commonly measuring 50 to 100 μm or more in diameter (Melamed et al, 1962, 1966). They have abundant, finely granular cytoplasm and a cytoplasmic membrane that is either sharply defined or ragged with adherent platelets. The **nuclei are large and lobated, with well-defined chromatin structure. They contain multiple nucleoli, usually at least one in each lobe**, but these are sometimes difficult to see in Papanicolaou stain. Within the nuclei, there are also **multiple small areas of nuclear clearing**, emphasized as characteristic by McGrew (1965) (Fig. 43-4).

Megakaryoblasts are somewhat smaller than mature megakaryocytes and have much less cytoplasm, a large round or bilobed nucleus with more delicate chromatin, and one or several nucleoli.

In postpulmonic pulmonary venous and peripheral blood, megakaryocytes are less numerous, sausage-shaped, and typically stripped of parts of the cytoplasm. Their nuclei are contracted or fragmented and usually dark-staining, though still lobated. Nuclear chromatin detail is often obscured (Fig. 43-5). Megakaryocytes have been described by us (Melamed et al, 1962, 1966) and others (Minot, 1922; Raker et al, 1960; Jackson, 1962; Hume et al, 1964) in peripheral blood of healthy individuals and patients with and without cancer. A megakaryocyte blood count is possible. Preliminary counts on normal individuals have shown marked individual variation without apparent hematologic abnormalities (Efrati and Rozenszagn, 1960; Melamed et al, 1966; Hansen and Pedersen, 1978). These studies also document that megakaryocytes normally enter the blood circulation and that **platelet production**, thought to occur exclusively in the bone marrow, **may also take place in the lung** as these large cells pass through the narrow pulmonary capillaries.

Myeloid, Lymphoid, and Other Blood Cells

Some immature myeloid and lymphoid cells may be similar in size to small epithelial cancer cells and mistaken for them.

P.1548

The cytoplasmic granules in myeloid cells are indistinct with the Papanicolaou stain. Nuclei are rounded, reniform, or lobated. Nucleoli may be multiple and prominent, though they are rarely as large as those in many epithelial cancer cells. **Plasma cells and their precursors** may be recognized by the peripheral clumping of nuclear chromatin, often asymmetric positioning of the nucleus, and dark cytoplasmic staining with a paranuclear "hof" or clearing.

Figure 43-4 Megakaryocyte from the prepulmonic (azygos vein) blood. The cell is large with abundant granular cytoplasm and has a well-preserved, multilobulated nucleus with areas of clearing about many chromatin granules. (Seal's Nuclepore sieve method; H&E; oil immersion.) (From Melamed MR, et al. The megakaryocyte blood count. *Am J Med Sci* 252: 301-309, 1966.)

Large lymphocytes, monocytes, and mononuclear macrophages may measure as much as 20 μm in diameter. Usually, these cells have **bland-appearing nuclei and, occasionally, small nucleoli**. Poorly preserved cells of this type, or cells without specific characteristics, may be difficult to identify (Fig. 43-6). They can be mistaken for small cancer cells, particularly if they are degenerating and hyperchromatic. Such cells probably account for most of what are reported as unclassified "atypical" cells (Sandberg et al, 1959; Melamed et al, 1962; Nedelkoff et al, 1962).

Figure 43-5 Megakaryocytes from post-pulmonic (antecubital vein) blood. The nuclei are contracted (or fragmented) and have lost most of their cytoplasm. The cell in *A* is elongated as if distorted by passage through a narrow capillary. (Seal's Nuclepore sieve method; H&E; oil immersion.) (From Melamed MR, et al. The megakaryocyte blood count. *Am J Med Sci*, 252:301-309, 1966.)

Endothelial and Other Cells

Endothelial cells can be dislodged by the needle as a specimen of blood is obtained. They may be present singly, in small sheets, or even as syncytia. They have **delicate, transparent cytoplasm and regular, round or oval nuclei of 10 to 15 μ m diameter with very delicate or finely punctate chromatin and at least one, sometimes prominent, nucleolus**. It is worth deliberately preparing a few specimens that contain endothelial cells because their normal appearance is quite characteristic, though, like all other cells, there are circumstances in which they can become quite atypical

P.1549

(Fig. 43-7). If necessary, their identity can be confirmed by immunostaining with Factor VIII or CD31.

Figure 43-6 A binucleated cell from antecubital venous blood of a patient following mastectomy for breast carcinoma. Classification is uncertain. (Seal's Nuclepore sieve technique; H&E; oil immersion.)

Epithelial (squamous) cells from the skin have been identified in blood specimens obtained by percutaneous venipuncture. Similarly, **mesothelial cells** have been found in blood samples obtained by **transpericardial needle aspiration of the heart**. These cells are morphologically identical to those observed in other types of preparations and should be readily recognized.

Among other unusual cells that have been identified on rare occasion are **trophoblasts** (Douglas et al, 1959), **osteoclasts** (Haemmerli and Straeuli, 1963), **Gaucher cells**, and **mast cells** (Alexander and Spriggs, 1960).

Significance of the Early Studies

In early studies, the likelihood of finding cancer cells in the blood of patients known to have cancer was variously reported from less than 1% to as much as 96.5% (McGrew et al, 1960; Christopherson, 1965; Goldblatt and Nadel, 1965; Griffiths, 1965; Griffiths et al, 1973; Nagy, 1965). In our own experience at that time, principally with patients having lung and breast cancer, cancer cells were found in the peripheral venous blood of less than 1% of the patients. Some of the extraordinary differences in the published results can be attributed to technical differences in the method of processing, the use of peripheral versus regional venous blood, differences in the number and volume of samples examined, and differences in the type of cancer and stage of the disease. The likelihood of finding cancer cells was greater in regional venous blood draining the cancer site than in peripheral venous or arterial blood, greater when more specimens or larger volumes of blood were examined (Gurian and West, 1963), greater in disseminated cancer, and probably greater when tumor masses were disturbed mechanically by manipulation during surgery or physical examination (Jonasson, 1961; Breslow et al, 1968; Roger et al, 1972; Turnbull et al, 1965). It is also worth noting that specimens of blood and

perfusate from surgical specimens are not to be compared with blood samples drawn by venipuncture from the living patient. Selbach et al (1963) examined regional and inferior vena caval cadaveric blood from 18 patients who died of a variety of different carcinomas and found cancer cells in 50%. They attributed this to advanced disease rather than to any agonal or postmortem artifact. The study should be repeated with contemporary techniques.

Figure 43-7 Endothelial cells from peripheral venous blood of a patient with malignant melanoma. There is an unusual angular irregularity of nucleoli in these cells. (Seal's Nuclepore sieve technique; H&E.)

The early studies of circulating cancer cells, though of relatively limited clinical value, provided a foundation for subsequent investigations using the new technologies described below. They identified the types of cells that may be observed, in small number, in the circulating blood and contributed to our understanding of megakaryocytic circulation and platelet formation (see above).

In retrospect, it is not surprising that the reported presence of circulating cancer cells and its relationship to metastasis and survival of patients with cancer was (and still is)

P.1550

controversial. Engell (1959), in a follow-up of his earlier report, Potter and Malmgren (1958), and Song et al (1971), failed to demonstrate a convincing relationship between the presence or absence of circulating cancer cells, metastases and survival. On the other hand, Watne and associates (1960) did find a somewhat higher proportion of potentially curable patients among those who had no circulating cancer cells. Drye et al (1962) reported that the likelihood of tumor recurrence was greater in patients who had cancer cells in peripheral blood than in those who did not.

Roberts et al (1958, 1960, 1961a, 1961b, 1962), Cole et al (1961) and Jonasson et al (1961) described showers of tumor cells in the blood of patients immediately following surgical

manipulation or trauma to their tumor and reported that those patients had a 2- to 5-year survival rate that was half that observed in patients without such findings during surgery. After 5 to 10 years follow-up, survival was unrelated to the finding of cancer cells in the blood, except when they occurred in showers, during or after operation (Roberts et al, 1967).

Figure 43-8 Cancer cells from aortic blood of rats with experimental cecal tumors produced by implantation of Walker 256 carcinosarcoma. Aliquot portions of the blood produced subcutaneous tumor growth when injected in other animals. *A*. From an animal with widespread metastases. *B*. From an animal with gross tumor only in cecum and regional lymph nodes. (Seal's Nuclepore sieve technique; H&E; *B*, oil immersion.)

Some of the most rewarding early work came from studies of factors influencing metastases in experimental tumors of animals (Fig. 43-8A,B). With an experimental carcinoma of the cecum in rats, for example, the appearance of cancer cells in the blood was related to the development of metastases (Agostino et al, 1959; Clifton and Agostino, 1961). Manipulation of a

transplanted Walker 256 carcinosarcoma in the thigh of a rat was shown to cause showers of tumor

P.1551

cells in the blood (Romsdahl et al, 1965). The circulation and distribution of injected cancer cells was followed by Griffiths and Salisbury (1963) and Hengesh et al (1962) and the viability of circulating cancer cells in an experimental system was demonstrated by injection of blood samples into other susceptible animals (Jonasson, 1958; Lee et al, 1976).

Even in dealing with known viable cancer cells, relatively large numbers must be introduced into the blood circulation before survival and growth are assured. As has been shown in early studies, the probability of tumor "take" and growth in the experimental animal is directly related to the number of cells inoculated (Baserga et al, 1960; Fisher and Fisher, 1959; Overstreet and McDonald, 1957). Yet, the finding of tumor cells in the blood of patients with cancer, and the fact that some cells may pass through an autotransfusor unit, has become a **potential contraindication to intraoperative autotransfusion in cancer patients** (Yaw et al, 1975) and to their use as elective blood donors (see leukapheresis studies below).

Factors affecting survival and distribution of cancer cells in the blood, and their potential ability to invade and proliferate, are of great interest in understanding the mechanism of blood-borne metastases. The early descriptions of the fate of tumor emboli by Takahashi (1915), Warren and Gates (1936), and later by Saphir (1947) and Baserga and Saffiotti (1955), were further clarified by Wood (1958) and Zeidman (1961), who carried out direct observations of the circulation by phase microscopy and microcinematography in living animals. They demonstrated that many intra-arterially injected tumor cells may lodge promptly in the arteriolocapillary bed and become adherent to endothelium, but many surprisingly large tumor cells became greatly elongated and passed through the capillary bed. Physical factors, such as capillary diameter, cell size, and flow rate, appeared of little importance in determining whether the cancer cells will lodge. Rather, it was thought that inherent characteristics of the cell itself (Fidler et al, 1977), derived by clonal evolution of tumor cell subpopulations (Nowell, 1976), enable the successive steps of invasion, detachment and embolization, lodging, and growth at selected sites that constitute the development of metastasis. The invading tumor cell has lost intercellular and substrate junctions and exhibits increased enzymatic activity at its interface with the extracellular matrix. Within minutes after the tumor cell lodges and adheres to capillary endothelium, it is enmeshed in a thrombus. This is followed by evidence of endothelial injury. Leukocytes accumulate and then penetrate the endothelium, leaving defects that are utilized for the migration of other leukocytes, as well as the cancer cells. Tumor cells are seen to reach the perivascular connective tissue within 3 hours (Pauli, 1983).

Blood coagulation appears to play an essential role in the very early development of metastases. Cancer cells are rich in thromboplastin (Lawrence, 1952), promoting thrombus formation and endothelial adhesion. Heparin and fibrinolysin, which interfere with thrombus formation, are known to decrease the incidence of metastases in experimental animals (Cliffon and Grossi, 1956; Wood et al, 1957; Grossi et al, 1960; Cliffon and Agostino, 1961; Fisher and Fisher, 1961, 1964).

CONTEMPORARY METHODS OF IDENTIFICATION OF CIRCULATING CANCER CELLS

Immunocytochemistry

Cancer cells that detach from solid tumors and enter the blood circulation are quickly trapped in

capillaries of organs, such as lung and liver, and most die. Some of the cells **lodge in the bone marrow** and those that survive can accumulate in numbers far greater than the cells **in transit** in the blood. Marrow is relatively accessible for study and offers a good opportunity to find circulating epithelial cancer cells. But, even in well-prepared specimens examined by conventional cytologic techniques, it has been exceedingly difficult to identify single cancer cells among the great many immature marrow cells. Thus, efforts were undertaken to identify nonhemopoietic cells in these specimens by means of special stains. **Immunocytochemical stains** have become the method of choice. In one of the earliest applications, Herbeuval et al (1965) identified megakaryocytes in peripheral blood by immunofluorescent staining and suggested that differences in antigen expression could be a useful parameter for recognizing circulating cancer cells. The recent extraordinary advances in cell classification by immunocytochemistry, and growing numbers of highly specific polyclonal and monoclonal antibodies, have taken us a long way in this direction. With the introduction of sophisticated molecular genetics into diagnostic cytology, still more powerful tools are now available for detection of cancer cells that are not easily identified by morphology alone.

Yet, while these represent major technical achievements, **it is still not clear whether a finding of tumor cells in blood or marrow has independent prognostic importance or should guide therapeutic decisions** (Funke and Schraut, 1998; Ghossein et al, 1999). The results of studies on human cancers, summarized below, are not conclusive. Whether this is due to limited specificities of the markers used to detect and identify the cancer cells, with misinterpretation of benign cells as tumor cells, or because the detected cells are nonviable, hibernating, or kept in check by some host defense mechanism, is still a matter of speculation.

Immunocytochemical Techniques

Epithelial cytokeratins are the most commonly used tissue-specific markers. They are a major constituent of carcinomas and are not found in the hemopoietic cells of blood or marrow. Other markers used in a number of studies include **prostate specific antigen (PSA)**, which is found only in cells of prostatic epithelial origin; **tyrosinase**, which is expressed in melanoma, and, less commonly, **carcinoembryonic antigen (CEA)** and **mucin antigens**, observed in adenocarcinomas. Cells characterized by the presence of these, or a growing number of other tissue-specific constituents

P.1552

and cell-surface markers, can be **identified by fluorescence or enzyme-tagged monoclonal or polyclonal antibodies** in smears of blood or marrow. Typically, this occurs after enriching for the tumor cells by density gradient or immunomagnetic separation. Generally, the maximum sensitivity of this technique detects one tumor cell among 10^5 to 10^6 nucleated cells in blood or marrow (Osborne et al, 1991).

Double Labeling

By labeling **breast cancer cells** with both EMA (epithelial membrane antigen) and an antibody to estrogen receptor (ER), Berger et al (1987) were able to distinguish ER-positive and ER-negative tumor cells. They established, in principle, the possibility of identifying and characterizing **circulating cancer cells immunocytochemically** in ways that might predict their potential to form metastases and/or respond to therapies.

Immunomagnetic Cell Selection

This is a recently proposed technique to enrich for epithelial tumor cells in blood or marrow. It relies on lineage-specific cell markers to separate out the tumor cells (see below). Antigens, known to be on the tumor cells, and not present in blood or marrow cells, are labeled with **antibody conjugated to magnetic microbeads**. Labeled cells are separated from unlabeled cells in a magnetic field, usually by passing the cell suspension through a magnetic gradient column or using a magnet to retain the labeled cells in a pellet, while decanting the supernatant (Hardingham et al, 1993; Berois et al, 1997; Eaton et al, 1997; Martin et al, 1998; Naume et al, 1998; Racila et al, 1998; Witzig et al, 2002). Rye et al (1997) refined the procedure further by sieving through a 20 μ m nylon filter that retained the larger clusters of beads with adherent cells and allowed unbound beads and free cells to pass through. Estimates of 5- to 25-fold enrichment were reported and sensitivity was sufficient to detect one tumor cell in 10^5 to 10^6 nucleated cells. In an interesting modification of the technique, Naume et al (1998) used CD45 (leukocyte common antigen) coated beads to enrich for tumor cells by depleting the samples of leukocytes.

Reverse Transcriptase-Polymerase Chain Reaction

One of the strategies currently proposed for detection of circulating cancer cells in blood or bone marrow makes use of the **polymerase chain reaction (PCR)** to amplify line-age-specific nucleic acid of the target cells. Tumor cell-specific DNA sequences have been identified in hemopoietic neoplasms but, **except for Ewing's sarcoma/PNET** (see below), they have a limited role in identifying circulating cells of solid tumors.

Malignant cells generally continue to express the protein markers of their tissue of origin (lineage markers), which can be identified by immunocytochemistry as described above, but also by the presence of **messenger RNA (mRNA) for those proteins**. For details of these observations and technical principles, see Chapter 3. The reverse transcriptase procedure (**RT-PCR**) consists of two steps: first, mRNA extracted from the cells is incubated with appropriate primers and the enzyme reverse transcriptase (RT), which transcribes the mRNA back into a complementary DNA (cDNA). Then, using the PCR, the cDNA is amplified and its identity confirmed by gel electrophoresis (Southern blotting). RNA is unstable in an extracellular environment so, in general, its presence confirms the presence of intact cells. Reported sensitivities are in the range of one tumor cell in 10^6 to 10^7 nucleated cells of blood or marrow (see Raj et al, 1998 for a review). In experimental systems, immunomagnetic enrichment followed by RT-PCR was reported by Zhong et al (2000) to detect one tumor cell in 10^7 to 10^8 mononuclear cells, and by de Cremoux et al (2000) to detect one tumor cell in 5 ml blood. On the other hand, de Cremoux et al found **clinical samples positive by RT-PCR in 3 of 28 patients with benign breast disease**.

It is important to emphasize that **the method does not depend on identifying a cancer specific gene, but can be applied to any cancer for which a tissue specific (or lineage) gene is identified. This, though, is restricted to tissue samples that do not contain cells normally expressing that gene**. The extreme sensitivity of the PCR technique is its most important advantage and also its greatest disadvantage. False-positive reactions can result from contamination, or from amplification of the designated gene, which may be present, though expressed to a very limited extent, in other cells (illegitimate transcription). Finally, there is increasing evidence that **nucleic acid fragments and specific cellular antigens**, released from tumor cells, can be found in blood plasma in the absence of intact tumor cells (Wang et al, 2003; Ohno et al, 2003).

Fluorescent In Situ Hybridization

In a feasibility study, Muller et al (1996) **used anti-cytokeratin antibody labeling to identify breast cancer cells in the marrow together with fluorescence in situ hybridization (FISH) for detection of numerical changes of chromosome 17.** Multiple hybridization signals were observed in cell clusters. A specific probe to HER2/neu gave amplification signals in two of eight breast cancers but none in prostatic cancers used as controls. Soria et al (1999) investigated the value of **telomerase** as a marker for breast cancer cells (see below).

APPLICATIONS TO HUMAN TUMORS

Breast Cancer

Immunocytochemistry

Carcinoma of the breast has been one of the most intensively studied human cancers. In the many reports of immunofluorescence or immunocytochemical staining with various monoclonal and polyclonal antibodies to tissue-specific antigens, primarily cytokeratins, **tumor cells were said to be present in blood or marrow of from 10% to 45% of**

P.1553

patients at the time of diagnosis. They were considered to have significant prognostic importance by some investigators (Diel et al, 1992, 1996; Harbeck et al, 1994; Braun et al, 2000; Lyda et al, 2000; Gebauer et al, 2001), but of no independent prognostic significance by others (Schlimok et al, 1987; Berger et al, 1988; Ellis et al, 1989; Kirk et al, 1990; Salvadori et al, 1990; Singletary et al, 1991). The following reports are illustrative.

Selected Studies Showing Prognostic Significance

Dearnaley (1981, 1983) and Redding (1983) and their associates were the first to use immunocytochemistry to detect micrometastatic cells in aspirates of bone marrow by staining for **epithelial membrane antigen (EMA)**. In a subsequent long term follow-up study, Dearnaley et al (1991) reported that 11 of the 13 women who had EMA-positive cells in the marrow later developed clinically evident metastatic disease, whereas only 8 of 26 with negative marrow developed metastases. In another report from the same group, Coombes et al (1986) found cancer cells in the bone marrow of 60 of 269 patients at the time of diagnosis. Nineteen (32%) of those with tumor cells in the marrow relapsed after a median interval of 22 months, compared with 17% of patients without detected tumor cells.

Figure 43-9 Bone marrow aspirate from a patient with stage I breast carcinoma, demonstrating cells recovered from the interface layer of a Ficoll-Hypaque density gradient and reactive with fluoresceinated antibody to epithelial cytokeratins and cell membrane antigen. A cluster of four cells of breast cancer photographed by phase microscopy (*A*), and the same field photographed by fluorescence microscopy (*B*). Another field showing three nucleated single cells by phase microscopy (*C*), and one of those cells (a breast cancer cell) exhibiting fluorescence by fluorescence microscopy (*D*). The *arrows* (*C*) point to two nucleated hemopoietic cells that do not fluoresce. (Reprinted with permission from Cote et al. *Am J Surg Pathol* 12:333-340, 1988.)

Cote et al (1988) and Porro et al (1988), using **monoclonal antibodies to cell membrane and/or cytoskeletal antigens**, found immunoreactive tumor cells in the bone marrow of from 17% to 27% of patients with node negative breast cancer. The number of tumor cells increased in more advanced tumors (Fig. 43-9). In a follow-up report, Cote et al (1991) found that the presence of **tumor cells in the marrow at diagnosis was significantly associated with early recurrence**.

Witzig et al (2002) enriched for tumor cells in lysed

P.1554

peripheral blood by **immunomagnetic separation** with anti-epithelial antibody-coated magnetic beads. They then stained with a cocktail of **anti-cytokeratin antibodies** and found tumor cells in 2 of 25 patients with node-positive cancer, none in 25 node-negative cancers, and 19 of 25 patients with metastatic carcinoma. Beitsch and Clifford (2000), who also used immunomagnetic separation to concentrate tumor cells, reported an 8-fold increase in the number of tumor cells from advanced, compared with early, tumors. Interestingly, they found a small number of contaminating squamous cells, confirmed morphologically (see “false positive”

below).

In one of the largest prospective studies with 6.5 years follow-up of patients with breast cancer, Solomayer et al (2001) reported finding cancer cells in bone marrow aspirates of 43% of 727 patients. The tumor cells were identified by immunostaining with a monoclonal anti-mucin antibody. They concluded that cytochemically detected tumor cells in the marrow **had independent prognostic significance**. Naume et al (2001) reported another large study in which bone marrow aspirates from 920 women with primary breast carcinoma were enriched for tumor cells by density separation of mononuclear cells, and monocytes removed with CD45 conjugated immunomagnetic microspheres. They identified cytokeratin positive tumor cells in approximately 10% of node-negative and approximately 20% of node-positive patients. Janni et al (2001) suggested that bone marrow studies for tumor cells in patients with breast cancer be included as part of their follow-up examinations. They had shown that survival of patients with known distant metastases was significantly shorter for those with many cytokeratin-positive cells in marrow, compared with patients who had few or no such cells. They then compared marrow aspirates at the time of primary diagnosis with marrow examined after a median interval of 19 months. Of 89 patients in their report, 24 presented with tumor cells in the marrow at the time of primary diagnosis, 10 of the 24 had persistent tumor cells at follow-up, and 15 who were initially negative, became positive in the follow-up specimen. **Those who were persistently negative had significantly better survival than patients with tumor cells in the follow-up specimen**. The latest study by Cristofanilli et al (2004) used a semi-automated fluorescent-based microscopy system (Cell Spotter Analyzer manufactured by Veridex) to detect cytokeratin-labeled circulating cancer cells in 177 women with metastatic mammary carcinoma. The presence of 5 or more cancer cells in a 7.5 ml sample of peripheral blood indicated poor response to therapy and significantly lower survival. In an accompanying editorial, Braun and Marth (2004) cautioned against the adoption of these results as a guide to treatment without further studies.

Selected Studies Showing No Prognostic Significance

Using **anti-EMA antibody**, Mansi et al (1991, 1999) screened multiple bone marrow aspirates taken at the initial surgery of 350 patients with breast cancer and found tumor cells in 89 (25%). After follow-up periods of 8 years (1991) and 12.5 years (1999), they reported 10-year relapse-free and overall survival of 44% and 45%, respectively, for patients with detected tumor cells, compared to 63% and 65%, respectively, for patients without detected tumor cells. **But, when corrected for tumor size, lymph node status, and vascular invasion, there was no significant difference**.

Molino et al (1997) used a pool of **tumor-associated monoclonal antibodies** to identify tumor cells in the marrow of 34 of 109 patients with stages I-II breast cancer and also concluded that the **presence of tumor cells carried no independent prognostic significance**.

Effect of Therapeutic Interventions

As already noted, there were early reports that **tumor cells were released by manipulation at the time of surgery**. Choy and McCulloch (1996) reviewed this issue and reported finding cytokeratin-positive tumor cells in the effluent blood from breast carcinomas of 6 of 18 patients during surgery. Tumor cells were found in only 1 patient preoperatively and in none postoperatively. They reported a strong correlation between vascular density and the probability of tumor shedding into the venous circulation during surgery (McCulloch et al, 1995). Molino et al (1997) and Krag et al (1999) confirmed that the presence and number of tumor

cells in peripheral blood of patients rapidly declined over the next few hours and weeks following surgery.

The question **whether tumor cells are released by cytokine infusion** (granulocyte colony stimulating factor; stem cell factor, etc.), which may be given prior to high-dose chemotherapy, was investigated by Franklin et al (1999). They identified tumor cells in marrow, peripheral blood, or leukapheresis specimens by immunocytochemistry in 21 of 203 patients with breast carcinoma in stages II to IV, demonstrated no increase following cytokine infusion.

Peripheral blood specimens were reported by Lin et al (2000) to contain cytokeratin-positive tumor cells in RT-PCR preparations from patients with nasopharyngeal cancer undergoing irradiation. Whether this finding had any significance was previously questioned in a report by Cooper et al (1998) who found tumor cells in the infusions of bone marrow or peripheral blood progenitor cell samples given to 23 of 57 women undergoing high-dose chemotherapy. They found **no difference in the subsequent clinical course of those who received infusions with, or without, detectable tumor cells.**

Molecular Markers

Datta et al (1994) used an **RT-PCR assay for cytokeratin 19 (CK-19) to identify tumor cells in peripheral blood and bone marrow** of 34 women with breast cancer. They were able to identify tumor cells in peripheral blood of 4 of 19 stage IV patients. They found tumor cells in the bone marrow of 5 of 6 patients who were treated with ablative chemotherapy, followed by autologous bone marrow transplantation (the stem cell apheresis harvests were free of tumor cells). Interestingly, 1 of 39 control patients (with chronic myelogenous leukemia) had a false-positive reaction. Kruger et al (1996) reported CK-19 message detected in 14 of 26 blood samples and 14 of 24 marrow samples of breast cancer patients. Moscinski et al (1996) modified

P.1555

the technique to increase sensitivity and found histologically negative bone marrow to be positive for molecular markers in 14 of 30 patients, with false-positive reactions in marrow from 2 patients with chronic myelogenous leukemia. Fields et al (1996) used the same technique and found occult tumor cells in 52% to 82% of high-risk patients, expanding with increasing stage. The probability of **relapse, after high-dose chemotherapy and autologous marrow transplant, for patients with stage IV cancer, was 14% in the group with no occult tumor cells and 94% for those who had cancer cells.**

Schoenfeld et al (1997) compared RT-PCR with immunocytochemical stains for cytokeratin 19 (CK-19) in blood and bone marrow of 78 breast cancer patients who had no evidence of distant metastases. They identified CK-19-positive cells in peripheral blood of 5% and in marrow of 22% of patients by immunocytochemistry, and in 25% and 35%, respectively, by RT-PCR.

Soria et al (1999) took advantage of the fact that **cancer cells express telomerase**, whereas benign epithelial cells do not, and used telomerase activity as a marker for detection of cancer cells in the peripheral blood of patients with breast cancer. They found telomerase activity in the cells separated on immunomagnetic beads, coated with an epithelial specific antibody, from blood samples of 21 of 25 patients with stage IV breast carcinoma. Telomerase was undetectable in normal volunteers.

At the time of this writing (2004), there is considerable evidence that tumor cells are released into the circulating blood, are present in marrow of a substantial number of

patients with breast cancer, and can be found with increasing frequency in more advanced disease. There is no agreement, however, on an optimal methodology for detection of these cells and still no consensus on their prognostic significance.

Malignant Melanoma

There are few studies of malignant melanoma cells detected by cytologic examination of the blood. Mehta and Riddel (1965) reported finding melanoma cells in the peripheral blood of 4 of 12 patients with surgically "curable" melanoma and 6 of 10 patients with known metastases. Of 17 who were treated by isolated limb perfusion with chemotherapy, tumor cells were found in the perfusate from 12.

Smith et al (1991) were the first to use RT-PCR to detect small numbers of tumor cells in peripheral blood by expression of messenger RNA for the enzyme **tyrosinase**, a gene actively transcribed only in melanocytic cells. The technique was extremely sensitive. It was possible to detect a single cultured melanoma cell that had been added to 2 ml of blood. In a preliminary clinical study, Smith et al (1991) obtained positive reactions in 4 of 7 patients with malignant melanoma, but not in healthy subjects or patients with other cancers.

Battayani et al (1995) used RT-PCR of mRNA for tyrosinase to study the peripheral blood of 193 patients, with and without disseminated melanoma, and concluded that the presence of circulating melanocytes **predicted rapid relapse and progression of disease**. Mellado et al (1996) used the same technique in a prospective study of 91 patients and found a statistically significant association with stage of disease. Circulating melanoma cells were detected in 36% of localized stage I and II melanomas, and in 94% of patients with known metastases. Ghossein et al (1998) found tyrosinase mRNA in peripheral blood of 9 of 73 patients with malignant melanoma and in bone marrow of 18 of 109 patients. All control patients were negative. A positive reaction correlated inversely with overall survival, although it did not correlate with stage of the primary melanoma. Kunter et al (1996) also viewed RT-PCR of tyrosinase mRNA as a useful prognostic marker.

Foss et al (1995) failed to detect any circulating melanoma cells by RT-PCR in 36 patients with ocular uveal melanomas or in 6 patients with advanced cutaneous melanomas. The unique situation of ocular melanomas may explain those negative results (see Chap. 41). Curry et al (1998) described a prospective RT-PCR study of tyrosinase and melanoma antigen (MART-1) expression in 276 treated patients in whom a positive test successfully predicted recurrence in two-thirds of patients within 18 months, but was positive in one-third of the patients who did not have recurrences by that time.

Hoon et al (1995) increased sensitivity by using a combination of four melanoma-associated gene markers in a PCR assay, but at the expense of a small number of false-positive reactions. Pittman et al (1996) favored a single round of RT-PCR, instead of nested RT-PCR, to reduce effects of contamination and reported detecting tumor cells in 3 of 24 patients.

In most studies, the assays were carried out on extracts of nucleated cells but Kopreski et al (1999) found amplifiable **tyrosinase mRNA in serum** of 4 of 6 patients with melanoma. Whether this was due to circulating tumor cells or to a soluble product of the primary tumor is not certain.

Control subjects with melanosis, deeply melanotic skin, melanotic reaction to the sun, etc., have yet to be studied in sufficient number and at this time, it is still too early to confirm the clinical value of these observations (Goodall et al, 1963; Buzaid and Balch,

1996).

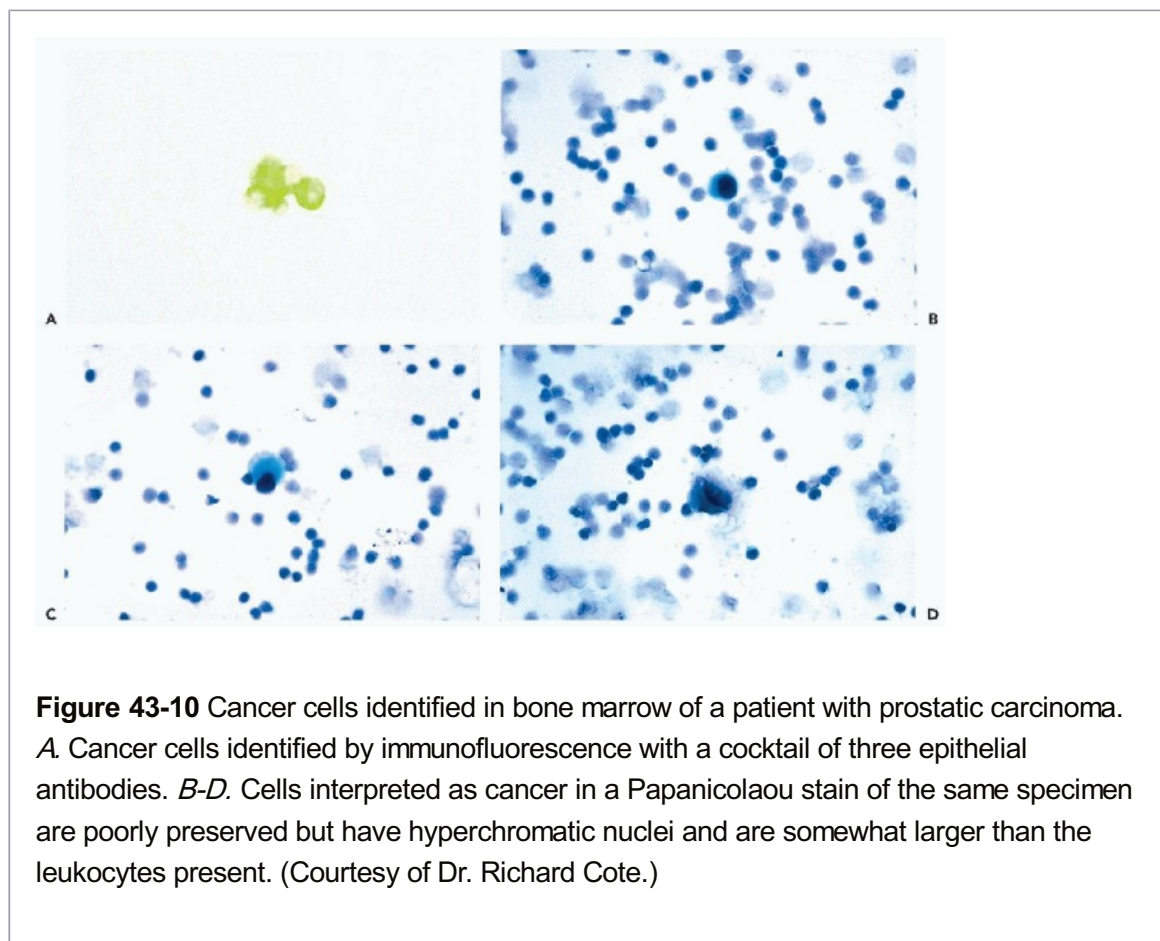

Prostatic Carcinoma

Immunocytochemistry

In a study undertaken some years ago by Bretton et al (1994) in our laboratory using a **panel of three monoclonal antibodies to epithelial membrane and cytoskeletal antigens**, 2 of 9 patients with localized prostatic carcinoma and 4 of 11 with known metastatic tumor had tumor cells identified in bone marrow aspirates (Fig. 43-10). **The number of antigen-positive cells correlated with stage of disease and, in patients with localized tumor, their presence correlated with PSA level.** Weckermann et al (1999, 2001) studied 82 consecutive patients who had bone marrow aspirates with pancytokeratin antibody, at the time of radical prostatectomy. After 4 years of follow-up, the patients with positive cells in the marrow had shortened relapse-free survival. The presence of tumor cells in the marrow was felt to

P.1556

be an independent risk parameter, unrelated to established factors.

Mansi et al (1988) used a mixture of antisera to epithelial and prostatic antigens and found tumor cells in the marrow of 11 of 15 patients with known metastatic disease and later (1999) in 21 of 36 patients with stage C carcinoma. **After androgen depletion therapy, 16 initially positive patients became negative.** Pantel et al (1997) identified from 1 to 38 cytokeratin-18-positive cells in samples of 2×10^6 nucleated marrow cells from 21 of 36 patients with stage C prostatic carcinoma. **After androgen deprivation therapy, 16 of the 21 patients had no tumor cells identified in the marrow and in 4 others there was a reduction in the number of cells.**

Molecular Markers

Most investigators have used **mRNA for PSA as a marker of prostatic epithelial cells** in the search for circulating cancer cells. In one of the earliest studies by this technique, Seiden et al (1994) found 5 of 65 men with clinically localized, untreated prostatic carcinoma who had evidence of cancer cells in peripheral blood. Surprisingly, in 7 other patients with newly diagnosed metastatic carcinoma, the test for circulating tumor cells was negative.

Ghossein et al (1995) examined the peripheral blood of 107 men with prostatic carcinoma and detected PSA mRNA in 4 of 25 patients with localized carcinoma (T1-2), 3 of 10 with more advanced carcinoma (T3-4, N+), and 25 of 72 with distant metastases. Using the same technique, Corey et al (1997) found positive marrow in 71% of patients undergoing radical prostatectomy and positive peripheral blood in 19% (with a somewhat higher percentage in the more advanced-stage patients). Moreno et al (1992) reported detecting PSA mRNA in venous blood of 4 of 12 patients with prostatic carcinoma.

Israeli et al (1994) compared RT-PCR for **prostate specific membrane antigen (PSM)**, which was positive in 48 of 77 patients with prostate cancer, to RT-PCR for PSA which was positive in only 7 of the same patients. They concluded that the more sensitive parameter was still highly specific, but it waits confirmation by others.

Sokoloff et al (1996) tried to measure tumor burden by quantifying mRNA for PSA and prostate specific membrane antigen in peripheral blood using a quantitative RT-PCR reaction. They examined specimens from 121 patients and found circulating PSA-producing cells in 29 of 33 patients with metastatic prostatic carcinoma. Also, positive reactions were found in 30 of 51 patients with pT1-2 tumors, and

P.1557

13 of 18 pT3 tumors. Given the high number of positive reactions in patients with pathologically confirmed localized tumor, they felt that the **PCR technique offered no benefit for preoperative staging. Whether it has prognostic significance remains to be seen.**

Using RT-PCR for PSA, Wood et al (1994) found tumor cells in 29 of 55 patients with prostatic carcinoma, whereas immunocytochemical stains for PSA were positive in 19 of the 24 RT-PCR positive cases in whom the test could be done. Several years later, Wood et al (1997) reported follow-up data on 86 patients who had clinically localized prostatic carcinoma when treated by radical prostatectomy. Two of 47 patients with negative RT-PCR for PSA and 10 of 39 who were positive at the time of surgery had recurrent tumor but, **after controlling for serum PSA levels, RT-PCR was not significant in predicting disease-free survival.**

Germ Cell Tumors and Ovarian Carcinoma

Fan et al (1998) examined cells derived from blood and separated by a process known as apheresis from 28 male patients with germ cell tumors using **PCR with primers for Beta human chorionic gonadotropin (hCG)**. In 7 of 20 patients who had Beta hCG-secreting tumors, the PCR for hCG was positive. Patients whose tumors did not secrete Beta hCG and patients with non-germ-cell tumors were PCR negative. They concluded that the finding of Beta hCG mRNA by PCR strongly suggested the presence of circulating tumor cells in patients with germ cell tumors.

Hildebrandt et al (1998) compared immunocytochemical staining for cytokeratin with RT-PCR for **germ cell alkaline phosphatase** in 20 patients with germ cell tumors. They identified tumor

cells in peripheral blood of 3 patients by immunocytochemistry, compared to 7 patients by RT-PCR. Using these techniques, they later found tumor cells in harvests of peripheral blood progenitors from 16 of 57 patients (Hildebrandt et al, 2000).

There have been very few studies of **ovarian carcinoma**. Braun et al (2001) found **cytokeratin-positive tumor cells** in the marrow of 32 of 108 patients with stages I-III ovarian carcinoma. Their presence was **associated with a high probability of distant metastases and death**. Double immunocytochemical staining for erbB2 overexpression of cytokeratin-positive cells in the marrow predicted greater risk of relapse and death for erbB2-positive, compared to erbB2-negative, tumor cells.

Neuroblastoma

In an early study of **bone marrow from neuroblastoma patients**, Moss et al (1991) used a mixture of immunoperoxidase-labeled monoclonal antibodies to neural and neuroblastoma antigens to stain the tumor cells and identified them in 67% of 197 newly diagnosed patients, compared to 46% by conventional cytologic examinations. Tumor cells were detected by immunocytology in 34% of patients otherwise considered to have localized or regional disease. For patients older than 1 year, the presence of occult tumor cells in marrow was a significant predictor of poor outcome.

Mattano et al (1992) were among the first to report identifying **neuroblastoma tumor cells in peripheral blood by RT-PCR**. They were able to detect a **neuroendocrine protein gene product** in 8 of 18 patients. Miyajima et al (1995) used RT-PCR to amplify the mRNA for **tyrosine hydroxylase**, the first enzyme in catecholamine synthesis, which they found in peripheral blood specimens of 8 of 14 patients, and in bone marrow of 18 patients, including 6 without cytologic evidence of tumor cells in the bone marrow. The RT-PCR assay for tyrosine hydroxylase mRNA was used **in combination with anti-ganglioside GD2** immunocytochemical stain by Lode et al (1997), who identified neuroblastoma cells within the CD34+ stem cell population obtained from peripheral blood of 17 neuroblastoma patients. They found greater numbers of tumor cells in patients with stage IV disease.

Ewing's Sarcoma

Ewing's sarcoma is the only solid tumor for which there is a **tumor-specific DNA marker**. The tumor is known to carry a **specific transcript resulting from fusion of the EWS gene on chromosome 22 to either of two protooncogenes, FLI-1 on chromosome 11 or ERG on chromosome 21** (see Chap. 36). Using RT-PCR to detect these **chimeric transcripts**, Peter et al (1995) and Pfeiderer et al (1995) identified Ewing sarcoma cells in bone marrow of as many as a third of their patients, and in peripheral blood of 5% to 20%. West et al (1997) reported positive bone marrow in 3 of 16 and positive peripheral blood in 3 of 10 newly diagnosed patients. Among patients with metastatic or relapsed tumor, 6 of 12 had positive marrow or peripheral blood. Zoubek et al (1998) found tumor cells in the marrow of 7 of 23 patients with clinically localized tumor at diagnosis and in 9 of 12 with metastases, including all with bone metastases.

Carcinomas of the Gastrointestinal Tract

Immunocytochemistry

Esophageal Carcinoma

Using an immunocytochemical stain for cytokeratins 8, 18 and 19, Thorban et al (1996) reported finding cytokeratin-positive squamous cancer cells in iliac bone marrow from 37 of 90 patients with carcinoma of the esophagus. Of the 42 patients who had resectable tumors, 19 had tumor cells in marrow and 15 relapsed, whereas only 3 of 23 who did not have tumor cells relapsed in the same time period.

Gastric and Colorectal Carcinoma

Using an anticytokeratin immunocytochemical stain, Schlimok et al (1990, 1991) found tumor cells at the time of surgery in the marrow of 34 of 97 patients with gastric carcinoma (1991) and 42 of 156 patients with colonic carcinoma. Confirming the latter findings, Lindemann et al (1992) reported immunocytokeratin-positive tumor cells in the marrow of 28 of 88 patients with radically resected colorectal carcinoma. The patients with immunopositive

P.1558

cells in the marrow had a significantly shortened time to relapse. Bone is not a preferred site of metastasis for colonic carcinoma but the authors felt that the presence of tumor cells in marrow indicated wider dissemination than generally thought.

Flatmark et al (2002) suggested **enriching for tumor cells** in bone marrow of patients with colorectal carcinoma by incubating the gradient-separated mononuclear cells with **magnetic 4.5 µm beads, coated by an anti-epithelial antibody** (similar to a procedure used by Naume, 1998, cited above), and retaining them with a strong magnet, while unbound cells are decanted. They found bead-rosetted tumor cells in 46 of 275 colorectal cancer patients, with false-positive findings in 3 of 206 control individuals.

Molnar et al (2001) emphasized the presence and potential significance of tumor cell clusters in peripheral blood of patients with colorectal cancer detected by immunomagnetic separation and pancytokeratin labeling of tumor cells in the buffy coat.

Pancreatic Carcinoma

Thorban et al (1999) found cytokeratin-positive tumor cells in aspirates of iliac marrow from 25 of 48 patients with **ductal carcinoma of pancreas**. Thirteen of 15 patients who had undergone complete resection of tumor, but had tumor cells in the marrow, suffered local or distant recurrence of tumor, whereas there were no relapses during that same time interval for the 12 patients who had identical surgery but were without tumor cells in marrow.

Molecular Markers

These techniques have been applied in studies of a small number of patients with carcinomas of various organs. Peripheral blood samples of 9 patients each, with **gastric and pancreatic carcinomas**, were examined for **cells expressing CEA** using RT-PCR; cancer cells were identified in 3 of the 9 pancreatic, and 2 of the 9 gastric carcinoma patients. Control patients, primarily with pancreatitis or gastritis, were negative (Funaki et al, 1996).

Gerhard et al (1994) used **CEA-specific RT-PCR** to examine bone marrow of 15 patients with **abdominal carcinomatosis due to colorectal, gastric, and pancreatic carcinomas** and found 10 to be positive, including 4 with presumed tumor cells not identified by immunocytology. Using the same technique, Castells et al (1998) detected CEA-positive cells in peripheral blood of 39 of 95 colorectal cancer patients and, interestingly, **in 5 of 9 patients with inflammatory bowel disease**. Although there was increasing probability of a positive finding with increasing stage of disease, there was **no firm evidence that (CEA) mRNA in peripheral blood is**

predictive of metastases.

Lung Cancer

Interest in the dissemination of lung cancer cells was among the primary motivations for studies of circulating cancer cells. Using an early technique for concentrating and identifying cancer cells in peripheral blood, Nedelkoff et al (1962) reported finding unequivocal cancer cells in only 2 of 192 patients with lung cancer; 24 other patients had abnormal, but nondiagnostic, cells present. Essentially similar reports of the rarity of cancer cells in peripheral blood were published by Sakurai et al (1962) and Scheinin and Koivuniemi (1963), though they identified malignant cells in pulmonary venous blood of as many as 18% to 22% of patients. Scheinin and Koivuniemi (1963) stressed that **lung cancer cells had to be differentiated from megakaryocytes in the pulmonary circulation.**

Cote et al (1995) used a cocktail of **antikeratin antibodies** to identify tumor cells in bone marrow of 17 of 43 patients with **non-small-cell lung cancer** who had no other evidence of metastases. Similar observations were reported by Pantel et al (1996) and Ohgami et al (1997). The presence of epithelial immunoreactive cancer cells in bone marrow was considered to be a significant independent predictor of relapse in node-negative patients in all three studies.

Stahel et al (1985) studied patients with **small-cell lung cancer (SCLC)**. They used a **monoclonal antibody against a surface antigen** of SCC (small-cell carcinoma) in an indirect immunofluorescence stain of bone marrow and found tumor cells present in 18 of 29 patients at initial staging. Considering that the 2-year mortality of SCLC approached 100% at that time, it is likely that wider sampling would have yielded an even greater number of positive cases.

A number of investigators have used CK-19 mRNA as a marker of lung cancer cells. **Reverse transcriptase-polymerase chain reaction** was reported to have a sensitivity of as high as one cancer cell in 10^7 nucleated blood cells. Peck et al (1998) reported detecting cancer cells in approximately 40% of non-small-cell and 27% of small-cell carcinomas, while others reported false-positive results due to illegitimate transcription (Dingemans et al, 1997). Neuroendocrine transcripts also have been studied as potential markers of circulating cancer cells, primarily for SCLC. Lacroix et al (2001) evaluated RT-PCR assays of 7 neuroendocrine markers and concluded that preprogastrin-releasing peptide was most specific and most sensitive; 13 of 26 patients with SCLC had positive blood samples and 5 of 23 had positive sputum samples. Also, 25 of 92 patients with non-small-cell lung cancer had positive blood samples. Whether this indicates the presence of intact and viable circulating cancer cells is still uncertain. Okusaka et al (1997) reported that serum levels of progastrin-releasing peptide increased during relapse of SCLC.

In an interesting study reported by Masson et al (1989), 7 of 8 patients with **lymphangitic metastases in lung** from various carcinomas were found to have **cancer cells in the wedged pulmonary artery blood.**

Carcinoma of the Uterine Cervix

Cancer cells in bone marrow aspirates were the subject of a recent study by Janni et al (2003) who identified isolated tumor cells by immunocytokeratin stain in 38 of 130 patients with newly diagnosed invasive cervical carcinoma. The presence of tumor cells was an independent risk factor

for subsequent distant metastases but did not correlate with overall survival.

Molecular techniques were used in a study by Stenman et al (1997) who used **RT-PCR of the mRNA for a squamous cell antigen** to detect squamous cancer cells in peripheral blood. They reported circulating cancer cells in 6 of 15 patients, 3 of whom subsequently relapsed; however, 2 of 9 patients without evidence of circulating tumor cells also relapsed or progressed. **Two pregnant women, at term, who were in the control group were also positive, possibly because of amnion or other fetal cells.**

In another application of the RT-PCR technique, Pao et al (1997) identified **human papillomavirus (HPV) type 16 specific mRNA** in peripheral blood samples from 12 of 13 patients who had advanced carcinomas of cervix.

Bladder Cancer

Uroplakins are specific membrane proteins of urothelial umbrella cells and are useful markers of metastatic transitional cell carcinoma (Moll et al, 1995; see also Chaps. 22, 23, and 26). Li et al (1999) developed an **RT-PCR assay for mRNA encoding Uroplakin 11**, which could be detected in peripheral blood from 3 of 10 patients with metastatic urothelial cancer, but was not found in 50 patients with nonmetastatic tumors or in 10 healthy volunteers. The potential high specificity of this marker makes it attractive for immunocytochemistry and immunomagnetic separation of urothelial cells in various metastatic sites (see Chap. 26). Whether it will prove to be of prognostic value still remains to be seen.

Thyroid

Cells expressing the **thyroglobulin gene** were identified in peripheral blood samples from 7 of 78 patients with thyroid cancer; including 5 who had had metastases resected and were believed to be free of tumor at the time (Ditkoff et al, 1996). None of 6 patients with benign thyroid disease and none of 7 normal volunteers had blood specimens expressing the thyroglobulin gene.

Hepatoma

Patients with late-stage hepatocellular carcinoma often develop lung metastases and many who undergo hepatic resection, develop recurrent tumor in the liver. Using **mRNA for albumin as a marker**, Kar and Carr (1995) reported positive RT-PCR assays in peripheral blood of 16 of 17 patients with hepatoma in stages III and IV. The assay was negative in patients with stage I hepatoma and negative in 10 cirrhotic patients and 10 patients with metastatic carcinomas to liver. However, the possibility of false-positive reactions was raised in a report by Matsumura et al (1994) who found a positive reaction for albumin mRNA in nuclei of neutrophils and lymphocytes from normal volunteers. They considered **alpha fetoprotein (AFP) mRNA**, which is not present in normal nucleated peripheral blood cells, to be more specific for liver cells. But, although 17 of 33 patients with hepatocellular carcinoma had demonstrable AFP mRNA in peripheral blood, it was also detected in 2 of 13 patients with cirrhosis and 2 of 17 patients with chronic hepatitis. Komeda et al (1995) reported similar data in patients with hepatocellular carcinoma and had no falsepositive reactions in control subjects. On the other hand, Lemoine et al (1997) found AFP mRNA in more than half of 64 patients operated for a variety of metastatic, as well as primary, tumors and nonneoplastic disease and concluded that it was not a specific marker of circulating cells from hepatocellular carcinoma. Thus, **at this time, there is no general agreement on an optimum marker for liver cancer cells in the circulation.**

VIABILITY OF CIRCULATING TUMOR CELLS

Given the surprisingly frequent finding of tumor cells in blood or marrow of patients, some of whom are expected to have a favorable outcome, **questions have been raised about the viability and tumorigenicity of these cells.** It is evident that not all cancer cells survive in the blood circulation. Many are obviously degenerating and nonviable when they are recovered; others must be incapable of surviving, even though they appear well preserved. Yet, the viability of at least some circulating cancer cells was reported by Moore et al (1958) who obtained tumor cell growth from blood of cancer patients in tissue cultures with a feeder layer of HeLa cells and by McDonald and Cole (1961) who demonstrated that at least some cancer cells in the regional venous blood of patients with colonic and rectal cancer were viable and could be grown in tissue culture. Roger et al (1972) reported finding tumor cells in mitosis in the regional venous blood of two patients receiving Colcemid. Gazet (1966) tried unsuccessfully to grow cancer cells in mice from the peripheral blood of patients. Joshi et al (1987) were able to grow malignant cells, similar to the primary tumor, in long-term tissue culture of aspirated marrow from 5 of 20 patients scheduled for autologous marrow transplantation. Clonogenic tumor colonies were grown from 21 of 26 peripheral blood samples containing immunocytochemically positive **breast cancer cells**, but not from specimens without detectable tumor cells (Ross et al, 1993). Solakoglu et al (2002) were able to culture viable tumor cells under special conditions from bone marrow in 124 (81%) of 153 patients with **carcinomas of breast, colon, and kidney**. They felt that the number of tumor cells grown in culture correlated with the probability of cancer related deaths.

Rill et al (1994) labeled the bone marrows harvested from 8 patients with **neuroblastoma** in clinical remission, with a **neomycin-resistant gene that served as a marker** and followed the patients who were reinfused with their own marrow (autologous transplantation) after high-dose chemotherapy. **In the 3 patients who relapsed, they identified the marker gene in malignant cells from marrow and other tumor sites, demonstrating that the bone marrow**

P.1560

contained viable cancer cells capable of forming tumors.

Mehes et al (2001) identified **cytokeratin- and mucinpositive** epithelial tumor cells in peripheral blood of 8 of 19 patients with advanced stage **breast cancer**, but the **majority of the cells appeared to be apoptotic**, as confirmed by demonstrating DNA strand breaks with the TUNEL assay. This study raised questions regarding the significance that can be attached to a finding of circulating cancer cells, without distinguishing intact from apoptotic (or necrotic) tumor cells.

Braun et al (2001) suggested that circulating ovarian and breast tumor cells, capable of establishing metastases, might be better identified by **double-labeling the cytokeratin-positive cells with antibody to erb-b2, which he reported to be an independent indicator of poor prognosis.**

RESULTS

False-Positive Results

Endogenous peroxidase activity of granulocytes and their precursors, if not completely blocked, can give **false-positive immunoperoxidase reactions**. Cytologic examination usually easily distinguishes these cells from epithelial tumor cells. Delsol et al (1984) reported

EMA expression on reactive and neoplastic **plasma cells** and some activated and neoplastic **lymphocytes**. Borgen et al (1998) emphasized that **alkaline phosphatase-labeled antibodies** give a **false-positive reaction with plasma cells**.

Zippelius et al (1997) examined the **specificity of primers**, commonly used in RT-PCR assays, by testing them against bone marrow from 53 control patients without epithelial malignancies. They found **false positive reactions** in a considerable number of control marrows with **epithelial glycoprotein-40, desmoplakin, CEA, erb-b2, erb-b3, prostate specific membrane antigen, and cytokeratin 18**. Bostick (1998) also found the **commonly used epithelial markers (except CK-19) falsely positive in the blood** of 13 normal control individuals. Only PSA mRNA was not detected by Zippelius et al (1997) in any of the 53 control marrow specimens. They emphasized that **a limiting factor in the detection of tumor cells by RT-PCR is the illegitimate transcription of tumor-associated or epithelial-specific genes in hemopoietic cells**.

Ko et al (1998) cautioned that **high sensitivities could be achieved for CEA in peripheral blood by increasing the number of PCR cycles, but doing so led to a marked increase in false positive signals**. De Cremoux et al (2000) came to a similar conclusion using RT-PCR for a MUC-1 specific cDNA sequence. With these limitations, some authors have concluded that PCR is not more sensitive than immunocytochemistry (Ko et al, 1998). If extracellular DNA is found in the plasma of other patients, as has been reported for women with mammary carcinoma (Silva et al, 2002), then the test is not likely to be specific.

A potential source of false-positive results is the **presence of small numbers of contaminating benign cells with a tissue-specific marker** that may have been introduced by an operative procedure or during collection of the blood or marrow specimens (e.g., squamous cells from the skin). Thus, **in all cases, careful cytologic examination is essential to confirm and classify marker-positive putative cancer cells**.

Other potential sources of false-positive findings are the observations that in bone marrow transplant recipients, the **stem cells** are capable of multiorgan differentiation. They have been shown to produce cardiac muscle cells (Orlic et al, 2001), hepatocytes (Alison et al, 2000; Theise et al, 2000), neurons (Mezey et al, 2003) and endometrium (Taylor, 2004). It is not known, at this time, whether any of these cells in bone marrow or circulating blood can be mistaken for cancer cells.

There is also substantial evidence that **fetal stem cells** may be transferred to the mother and persist for many years (Bianchi et al, 1996). These cells may invade a multitude of tissues and therein **produce differentiated cells of various types** (Khosrotehrani et al, 2004). Again, it is not known, at this time, whether any of these differentiated fetal cells may occur in bone marrow or peripheral blood and mimic cancer cells.

False-Negative Results

False negative results with RT-PCR may be the result of a number of factors. **Tissue inhibitors** of the PCR reaction can diminish sensitivity in some cases. The **marker of interest may not be expressed** by some tumor cells in a heterogenous population or it may be down-regulated by treatment; hence, it is usually advisable to combine several different markers. Intermittent shedding of tumor cells into the blood, or the random distribution of a very few tumor cells, may account for their absence in small samples of blood or marrow.

AUTOMATED SCREENING

The search for **immunocytochemically tagged** circulating tumor cells would seem to lend itself well to identification and quantitation by automated scanning instruments. Thus, Mansi et al (1988) proposed doing so in a search for breast cancer cells in bone marrow. They used the Leytas scanning and image analyzing microscope (see Chap. 46) and found it advantageous in cases with few tumor cells. Kraeft et al (2000) used an automated Nikon fluorescence microscope with CCD camera and a double-labeling protocol to minimize or eliminate false-positive staining. Pachmann et al (2001) used the CompuCyte Laser Scanning Cytometer (LSC) (see Chap. 47) to automatically scan for cells in peripheral blood that were stained by an immunofluorescent anti-epithelial antibody. After enriching with immunomagnetic beads, they were able to detect as few as 1 to 2 positive cells in a population of 10^7 nucleated cells.

Another apparatus, Cell Spotter Analyzer (Veridex) was recently used by Cristofanilli et al (2004) to detect cancer

P.1561

cells in peripheral blood of patients with metastatic breast cancer.

Figure 43-11 Cancer cells in thoracic duct lymph from a patient with disseminated malignant melanoma. Many of these huge cancer cells had cytoplasmic melanin. They were viable and grew in tissue culture, where they continued to produce melanin.

WOUND WASHINGS

It has been assumed that local recurrence of carcinoma, after potentially curative resection, may be due to **contamination of the operative wound by cancer cells** (Smith et al, 1963; Smith and Malmgren, 1964; Salsbury et al, 1965, 1973; Fisher et al, 1967). This type of recurrence is more likely with certain kinds of cancer, such as mammary carcinoma or epidermoid cancer of the mouth or pharynx. In an effort to predict which patients would suffer local recurrence, examinations of wound washings were carried out by Smith et al (1958),

Arons et al (1961), and Nash et al (1962) on specimens taken after surgery, prior to closure. Nash et al classified the specimens from 51 of 274 patients as positive, and 26 of the 51 had recurrent tumor. Arons et al (1961) reported cancer cells present in 26% of their cases, but subsequent clinical follow-up showed no correlation with local or distant metastases or survival.

An alternative explanation for postoperative local recurrence of tumor was proposed by Nash et al (1962), who suggested that cancer cell seeding in some wounds occurred after closure. They found support for this in the observation that cancer cells were sometimes present in the postoperative drainage of fluid from wounds that had yielded no such cells in previous irrigation specimens at surgery. Their observations should be viewed with skepticism, however, because the reactive and regenerating benign stromal and inflammatory cells might well mimic cancer cells and their work lacks clinical substantiation.

The problem of **differential diagnosis of tumor cells from actively proliferating connective tissue cells, endothelial and benign epithelial cells, and hematopoietic cells, is not to be underestimated.** One must have considerable experience with the type of specimens studied and maintain good clinicopathologic correlation if meaningful diagnoses are expected.

At the present time, wound washings are seldom obtained, except in cases of abdominopelvic surgery for carcinomas of the female genital tract, in which the finding of cancer cells in pelvic washings upgrades the stage of the carcinoma.

THORACIC DUCT LYMPH

Tumor cells have been identified in thoracic duct lymph from approximately 16% of patients with advanced cancers (Fig. 43-11). Technical problems of preparation and interpretation are somewhat simpler than for blood or wound washings.

In a remarkable study of the entire thoracic duct, its tributaries, and draining nodes, Young (1956) found involvement by carcinoma in 37%, and by lymphoma in 71%, of 150 patients with malignant neoplasms at autopsy. Burn et al (1962) reviewed the role of thoracic duct lymph in dissemination of cancer. Experience with the cytology of thoracic duct lymph is still too limited to suggest any clinical correlations.

Laboratory Techniques

Carol E. Bales

This work is dedicated to the memory of Grace R. Durfee BS, CT(ASCP), a pioneer of cytotechnology and the author of this chapter in the first two editions of this book (1961 and 1968).

P.1570

CYTOLOGIC TECHNIQUES

Over the years, cytopathology laboratories have experienced dramatic changes in the types and numbers of specimens submitted for cytologic evaluation. With the use of fiberoptic instruments and newer and more sophisticated imaging techniques guiding fine needle aspirations (FNA), cells can be obtained from almost all anatomic sites, presenting unique diagnostic challenges. More and more treatment decisions are being made on the basis of the cytologic diagnosis. The quality of the microscopic preparation being examined plays a major role in the cytopathologist's ability to make an accurate diagnosis.

In the past, the trained cytotechnologist frequently was also responsible for collection, preparation, and staining of material. As a result, many of the pitfalls affecting the quality of the microscopic preparations to be screened were learned firsthand. However, most laboratories now employ personnel whose primary and only function is cytopreparation, with the cytotechnologist participating solely in a supervisory capacity. A thorough understanding of basic cytopreparatory techniques is required to effectively oversee or modify these procedures according to the needs of a laboratory.

Descriptions of new techniques and automated procedures have been added to this chapter. Some of the older methods have been retained for historical purposes. A thorough understanding of the nature of the specimen is necessary to produce optimal results, regardless of the material and methods at one's disposal.

This chapter describes the basic techniques involved in cytopreparation, stressing the importance of the nature and type of the specimen rather than the site of origin.

Accurate cytologic interpretation of cellular material is dependent on:

- **Methods of specimen collection**
- **Fixation and fixatives**
- **Preservation of fluid specimens prior to processing**
- **Preparation of material for microscopic examination**
- **Staining and mounting of the cell sample**

These steps will be considered separately because of the important role each plays in affecting the quality of the microscopic preparation.*

A detailed description of the clinical methods involved in the collection of cellular material for cytologic evaluation can be found in chapters dealing with specific organs or organ systems. The principles of collection and processing of material by FNA are described in Chapter 28.

FIXATION AND FIXATIVES

Fixation of Smears

Ethanol Fixation

Rapid fixation of smears is necessary to preserve cytologic detail of cells spread on a glass slide that are to be stained by the Papanicolaou method. If smears are allowed to air-dry prior to fixation, marked distortion of the cells occurs.

In the past, the fixative of choice for gynecologic and other smear preparations was the one recommended by Papanicolaou, namely, a solution of equal parts of ether and 95% ethyl alcohol. Subsequently, it has been necessary to abandon this original and excellent fixative

because ether presents a fire hazard. **Ninety-five percent ethyl alcohol (ethanol)** is now employed as a fixative by most laboratories, with excellent results. This method of fixation may be used for all smears prepared at the side of the patient, such as vaginal, cervical, and endometrial aspiration smears; prostatic smears; breast smears; and aspiration biopsy smears. It is also used for the final fixation of all smears prepared in the laboratory from fresh fluids or those initially collected in 50% alcohol or other preservatives.

Smears should remain in the 95% ethyl alcohol fixative for a **minimum of 15 minutes** prior to staining. However, prolonged fixation of several days or even weeks will not materially alter the appearance of the smear.

To obtain ethanol without federal taxation, a license is required. Laboratories that do not have such a license may use other alcohols. However, to obtain results similar to those seen with 95% ethanol, different concentrations must be used. Table 44-1 shows equivalent concentrations of various alcohol fixatives as suggested and tested by Danos-Holmquist (1978).

These substitutes may also be used with membrane filters, except for 100% methanol that cannot be used for Millipore filters.

All alcohol fixatives should be discarded or filtered after each use with a good-grade, medium-speed filter, such as Whatman No. 1, and the concentration should be tested with a hydrometer before reuse.

TABLE 44-1 EQUIVALENT CONCENTRATIONS OF SEVERAL ALCOHOLS FOR PURPOSES OF CELL FIXATION	
100% Methanol	
95% Ethanol	
95% Denatured alcohol	
80% Propanol	
80% Isopropanol	

P.1571

Wet fixation with alcohol is recommended for all nongynecologic material to be stained by the Papanicolaou method. For gynecologic material, coating fixatives may be used.

Coating Fixatives

A number of agents on the market today can be sprayed or applied with a dropper to freshly prepared smears, thus eliminating the use of bottles and fixing solutions. Hairspray with high alcohol content was, at one time, effective as a fixative, but it is no longer considered suitable for this purpose. There are numerous cost-effective Pap smear collection kits and aerosol sprays currently available that produce excellent results. Most of these agents have a dual action in that they fix the cells and, when dry, form a thin, protective coating over the smear. These fixatives are particularly helpful if the smears must be mailed to a distant cytology laboratory for evaluation. The method is **not recommended** for smears prepared from fluids within the laboratory.

Instructions for applying the coating fixative accompany the product and should be followed carefully. Cans should be shaken well prior to each use to ensure optimal dispersal and adequate fixation. As in any good method of fixation, **the coating fixative should be applied immediately to fresh smears**. The distance from which the slides are sprayed with an aerosol fixative affects the quality of the cytologic detail. The optimal distance differs with the brand of fixative used (see Appendix to Chap. 8). Danos-Holmquist tested several spray fixatives and found that the distance of 10-12 inches was optimal. For details, see Table 44-2. There is a widespread tendency to hold the can too close to the slide; therefore, if you are experiencing suboptimal results with the spray fixative used by your clinicians, it should be tested for optimal distance. Aerosol sprays are **not recommended for bloody smears** because they cause clumping of erythrocytes. Coating fixatives may also be prepared inexpensively within the laboratory. Two such methods are given below.

TABLE 44-2 QUALITY OF CYTOLOGIC DETAIL WITH AEROSOL FIXATION AT VARIOUS DISTANCES

Fixative		Distance	Cytologic Appearance	Fixation	
Aqua Net* Hair	{	8-24 inches	Delicate chromatin detail	Good	
Spray		1-7 inches	Chromatin: hazy hypochromatic, nuclear shrinkage, cilia lost and cytoplasm distorted	Poor	
Richard Allen†	{	14-24 inches	Loss of chromatin detail; nuclear swelling	Poor	
Fixative		6-13 inches		Delicate chromatin detail	Good
		1-5 inches		Loss of chromatin detail; nuclear swelling	Poor

* Aqua Net hairspray, Fabergé Inc., 65 Railroad Avenue, Ridgefield, New Jersey 07657. (No longer recommended as a fixative.)

† Richard Allen Medical Industries, Inc., 1335 Dodge Avenue, Evanston, Illinois 60204.

Polyethylene Glycol (Carbowax) Fixative

(T. Ehrenreich and S. Kerpe, 1959)

95% Ethyl alcohol	50 ml
Ether [*]	50 ml
Polyethylene glycol	5 g

(Carbowax compound 1540)

* Ether may be eliminated and 100 ml of 95% alcohol used.

Soften the polyethylene glycol in an incubator at 56°C and add the 95% ethyl alcohol. Let stand for several hours at room temperature, or use frequent agitation to hasten the dissolution of the polyethylene-glycol. The solution may be dispensed in small dropper bottles.

Freshly made smears are placed on a flat surface and the slides are covered immediately by five or six drops of the fixative. Allow the slide to dry for 5 to 7 minutes or until an opaque, waxy film forms over the surface.

Diaphane Fixative

(G. N. Papanicolaou and E. L. Bridges, 1957)

95% ethyl alcohol	3 parts
-------------------	---------

Diaphane[†]

2 parts

[†] Diaphane is a synthetic resin made by Will Scientific, Inc., Rochester, NY.

Mix thoroughly at room temperature.

Fresh wet smears are placed on a flat surface and covered immediately with enough solution to form a thin coating over the slide—approximately 0.25 or 0.5 ml (5 or 6 drops) per slide. Allow the Diaphane coating to dry thoroughly (20 to 30 minutes) to a hard, smooth film that protects the

P.1572

smear. When smears are received in the laboratory, place in 95% ethyl alcohol to remove Diaphane before staining.

Processing of Smears Prepared With Coating Fixatives

Unless removed prior to staining, all coating fixatives will contaminate the staining solutions, particularly the hematoxylin. The water-soluble coating fixatives should be removed prior to staining by maintaining two separate dishes of 95% ethyl alcohol and leaving the slides in each dish for 5 to 10 minutes. The 95% ethyl alcohol used for washing off the coating fixative should be filtered or changed at least once each day, the number of times depending on the number of slides that are washed.

Manufacturers of spray fixatives occasionally use, in their products, concentrations of alcohol greater than those normally used for optimal fixation. This results in **increased cellular shrinkage**, which may cause loss of nuclear detail because of chromatin condensation. The increased density of the cell wall also can impede the penetration of light green dye, with resulting excessive cytoplasmic eosinophilia. Increasing the staining time in eosin-alcohol (EA) may give better cytoplasmic staining; however, better nuclear detail cannot be achieved. All commercial spray fixatives must be tested before acceptance and the results compared with smears that have been fixed in 95% ethyl alcohol.

Rehydration of Air-Dried Smears

Gynecologic Smears

In recent years, the use of unfixed, air-dried gynecologic smears has been advocated by some workers. Randall and von Amerongen (1997) recommend the submission of unfixed, air-dried smears and subsequent rehydration with 50% glycerin after arrival in the laboratory. They prefer this method over wet fixation because their educational efforts emphasizing proper fixation were ineffective when dealing with inexperienced medical staffs submitting small numbers of slides annually. A comparison in their laboratory of airdried and fixed cervicovaginal smears showed there was no significant difference between the two techniques in reference to their ability to detect abnormalities.

In our experience, even when dealing with large numbers of providers, air-drying artifact is less of a problem than it once was. This is most likely the result of years of education and the availability of inexpensive, easy to use fixatives and kits. However, if a laboratory receives large numbers of slides exhibiting air-drying artifact, and educational efforts have failed, this author thinks a more prudent alternative would be to rehydrate the defective slides rather than recommend that all slides be air-dried.

The rehydration procedure described below may be used for inadequately fixed smears. It must be noted that squamous cells may appear restored to a considerable extent after rehydration procedures whereas, in our experience, cells of secretory type often suffer irreparable damage.

The simplest rehydration technique that seems to work as well as, if not better than, most techniques was developed many years ago by R. G. Bonime of New York City (1966). Air-dried cytologic specimens are placed in a **50% aqueous solution of glycerin for 3 minutes** followed by two rinses in 95% ethyl alcohol prior to staining by the routine Papanicolaou method.

Nongynecologic Smears

Since inadvertent air drying prior to ethanol fixation may occur when slides are prepared by physicians and ancillary health care staff, Shidham et al (2001) recommend purposely air drying all smears and rehydrating them with normal saline after arrival in the laboratory. Proponents of the procedure judge the cytologic detail of brush smears and fine needle aspiration smears superior to smears made from the same material that were immediately and adequately wet fixed in alcohol. Advantages cited include lesser risk of cell loss and ease of collection by untrained personnel.

The author has no personal experience with the method and recommends testing it in one's own laboratory before adopting any permanent change in routine procedures.

Mailing of Unstained Smears

Unstained smears may be mailed to distant cytologic laboratories after the application of coating fixatives previously discussed. A variety of mailing containers are commercially available, ranging from plastic cylinders to cardboard containers and, if properly used, they will prevent breakage in the mail.

If coating fixative solutions are not available, the following method has been used for many years and gives very good results.

Glycerine Method

(J. E. Ayre and E. Dakin, 1946)

Smears are first fixed in 95% ethyl alcohol for a minimum of 15 minutes. The slides are then removed and one or two drops of glycerin are placed on the smear and covered with a clean glass slide. The slides may now be wrapped in wax paper and mailed to the laboratory in a suitable container.

Special-Purpose Fixatives

Neutral Buffered Formaldehyde Solution

37% to 40% Formaldehyde solution	100 ml
Water	900 ml
Acid sodium phosphate, monohydrate	4 g
Anhydrous disodium phosphate	6.5 g

Bouin's Solution

1.2% (saturated) aqueous picric acid	750 ml
37% to 40% Formaldehyde solution	250 ml
Glacial acetic acid	50 ml

These two fixatives are particularly valuable in preserving nuclear features in small samples, such as cell blocks.

Methanol Acetic Acid Fixative

Howell et al (1993) reported that **urine and bladder washings**, fixed with an equal volume of 20:1 methanol plus

P.1573

acetic acid (MA), produced cytocentrifuge preparations with well preserved cells and good cytologic detail.

An earlier study, comparing DNA histograms of fresh urine and bladder washing to an aliquot of the same sample fixed in MA, resulted in increased diagnostic accuracy when MA fixation was used (Deitch et al, 1982). Diagnostic accuracy of DNA histograms done on the same samples fixed with MA improved from 58% to 92% in urines and from 50% to 100% in bladder washings. Ethanol fixation usually resulted in DNA histogram deterioration. They recommend that the MA fixative be used when both cytologic evaluation and flow cytometry is desired on the same urine or bladder washing sample.

Balanced Salt Solutions

Nasuti et al (2000) reported that Normosol, a balanced salt solution, is suitable **for storage of fine needle aspirates**. In a comparison of paired FNA needle rinses, stored for up to 60 hours in Carbowax and Normosol, Normosol was superior for nuclear preservation and lack of obscuring background artifact. Normosol is an excellent, low-cost alternative for short-term storage of FNA samples.

Formol Alcohol

A number of workers have recommended varying mixtures of formalin and alcohol for fixation of smears and cell block samples. Tang et al (1997) reported that smears made from urinary sediment that had been prefixed in 60% alcohol and 3% Carbowax 1500, dried on a 40°C hot

plate for 15 minutes, and then fixed in 1:19 solution of 37% formaldehyde and absolute ethanol for 30 minutes retained significantly more cells than those fixed with 95% alcohol alone. The protein cross-linking properties of formalin may play a role in making the cells adhere better to the glass slide. Nuclear and cytoplasmic staining and detail were similar, exhibiting excellent morphology; however, the greater yield of cells in the formalin-alcohol mixture resulted in detection of a higher number of abnormal cases.

Nathan et al (2000) recommends the use of an **ethanol formalin fixative** for processing of cell blocks. This fixative results in excellent cytomorphic features that closely resemble the cytologic detail seen in Papanicolaou-stained smears. Preservation of histochemical and immunocytochemical properties are maintained. The fixative must be prepared fresh and used immediately because formalin is capable of oxidizing to formic acid. Nathan alcohol formalin substitute (NAFS) consists of a 1:9 solution of 40% formaldehyde and 100% ethanol. NAFS is added to spun-down cell pellets after the supernatant is discarded. After a minimum of 45 minutes, the sample is recentrifuged and the cell pellet wrapped in paper and placed into a cassette that is stored in 80% alcohol until ready for processing.

Saccomanno's Fixative

Saccomanno's fixative is 50% alcohol and approximately 2% Carbowax 1540 (www.ousc.com, Cat. #10063). Carbowax infiltrates and occupies submicroscopic spaces, preventing cell collapse, and thus protects the cells during air drying. Cells adhere well to glass slides as a consequence of air drying. This fixative, a variant of the fixative proposed by Ehrenreich and Kerpe in 1959 was first used by Saccomanno for prefixation of sputum but can be used for fluid specimens from other sites. Carbowax 1540 is solid at room temperature, with a melting point of 43° to 46°C. To avoid the necessity of melting it whenever the fixative is made, a **stock solution of Carbowax** can be prepared as follows: pour 500 ml of water or 50% ethyl alcohol into a 1,000-ml graduated cylinder. Melt Carbowax in an incubator or hot-air oven at 50° to 100°C. Add 500 ml of the melted Carbowax to the graduated cylinder. This mixture will not solidify and can be stored in a liter screwcap bottle.

A liter of **Saccomanno's fixative** can be prepared by mixing 434 ml of water, 526 ml of 95% ethyl alcohol, and 40 ml of the water or alcohol-based stock solution. The final concentration of alcohol will be slightly different, depending on which stock solution is used; however, this difference is not critical. Never use absolute alcohol for preparation of Saccomanno's fixative, since it may contain dehydrating agents that cause mucus to become hard and rubbery and difficult to blend.

Modifications have been recommended by various workers depending on the type of specimen being processed. The **Bales method** uses 2% carbowax and 70% alcohol for the final fixation of urinary sediment. Tang et al (1997) found that 3% carbowax gave a 3-dimensional appearance to cell clusters and that 60% ethanol was the optimal concentration of alcohol to ensure adequate fixation without protein precipitation.

Formalin Vapor Fixation

Some staining procedures require formalin vapor fixation. Place 1 to 2 ml of formalin solution of required concentration in a Coplin jar. Immediately after preparation of the smear, drop the slide into the Coplin jar, cell end up (label end down), and tightly cover the jar. The length of time required for fixation varies according to procedure.

Carnoy's Fixative

95% Ethanol	60 ml
Chloroform	30 ml
Glacial acetic acid	10 ml

This fixative will **hemolyze red blood cells** and, therefore, is useful for bloody specimens. However, shrinkage of the epithelial cells is greater than that observed in specimens fixed in 95% ethanol. The staining time in hematoxylin must be reduced to prevent overstaining. Place the bloody smear in Carnoy's fixative for 3 to 5 minutes, until the sediment becomes colorless, and then transfer to 95% ethanol or its equivalent. Nuclear chromatin will be lost if the cell sample remains in Carnoy's fixative for longer than 15 minutes.

This fixative must be prepared **fresh** when needed and discarded after each use. Carnoy's fixative loses its effectiveness on standing, and the chloroform can react with acetic acid to form hydrochloric acid. This fixative may be used for Millipore filters but will damage Nuclepore and Gelman filters.

LIQUID-BASED COLLECTION AND PROCESSING OF GYNECOLOGIC SPECIMENS

For many years, efforts have been made to develop methods that would enhance the sensitivity and specificity of the Papanicolaou smear. Emphasis has been placed on creating automated screening machines whose success depends on a representative sampling of cells on standardized slides containing a monolayer of well-stained, well-preserved cells.

From this research and development, liquid-based gynecologic specimen collection has evolved. Its proponents argue that liquid-based preparations outperform conventional smears because of improved fixation, decreased obscuring factors, and standardization of cell transfer. Proponents point out that, in direct smears, the cells are not transferred in a representative fashion and that up to 90% of the material scraped from the cervix may be discarded with the sampling device. With liquid-based collection, the sampling will be representative and operator-dependent variation will not occur since processing is controlled by the laboratory.

SurePath (TriPath Imaging, Inc, Burlington, NC) and **ThinPrep** 2000 System (Cytoc Corp, Marlborough, MA) are two such systems currently approved by the FDA for cervicovaginal testing. With both methods, the sample is collected in the conventional manner with one of the brush instruments (see Appendix to Chap. 8) but, instead of being spread onto a glass slide, it is transferred to a vial of fixative.

In the SurePath method, the sample is vortexed, strained, layered onto a density gradient, and centrifuged. Instruments required are a computer-controlled robotic pipette and a centrifuge. The cells form a circle 12.5 mm in diameter. The ThinPrep method requires an instrument and special polycarbonate filters. After the instrument immerses the filter into the vial, the filter is rotated to homogenize the sample. Cells are collected on the surface of the filter when a vacuum is applied. The filter is then pressed against a slide to transfer the cells into a 20 mm diameter circle.

Both methods result in a well preserved approximate monolayer of cells, with a background devoid of blood and mucus. However, the current high cost of these patented, commercial systems (i.e., \$55,000 for the ThinPrep 2000 System and over \$20.00 in cost of disposable materials for each specimen [Cytoc Corporation 2001 Price List]) is estimated to be the cost to implement the technique. This does not include the cost of retraining and recertification, required of cytotechnologists and pathologists in order to interpret the ThinPrep slides, which has led to the development and evaluation of alternative, less costly methods.

One such method referred to as SpinThin, developed by Khalbuss et al (2000), uses a **modified electric toothbrush** to release the cells into suspension from the collecting device. The cells are spun directly onto a 10 × 20 mm area of a glass slide using a Cytospin II cytocentrifuge with megafunnel. Results correlated very well with conventional smears and follow-up histology.

Another method described by Johnson et al (2000) places the cervical collection device into 15 ml of CytoRich Red (TriPath Imaging, Inc), a proprietary formula of buffering agents, emulsifiers, formaldehyde and alcohol. After arrival in the laboratory, cell suspensions are vortexed, poured through tulle (bridal veil fabric) and centrifuged. Following centrifugation, the supernatant is discarded and the sediment is vortexed. A drop of sediment is placed into an 8 ml Hettich cytocentrifuge chamber prefilled with 2 ml of CytoRich Yellow (TriPath Imaging, Inc), a proprietary Saccomanno-like fixative that prevents dehydration and collapse of 3-dimensional structures when slides are air-dried, and then spun onto adhesive-coated slides. Advantages include batch processing and reusability of its funnel assembly, which decreases the bulk of disposable plastic that can significantly impact the environment as well as add to the cost of individual tests.

Preliminary evaluation showed the method to be as efficacious and, in two instances, more specific than its conventional smear counterpart.

The cytopathology community is still assessing the relative efficacy of the costly liquid-based methods compared to that of the conventional smear. It remains to be seen whether the new technology will improve the prevention of cervical cancer (Bishop et al, 2000). One clear advantage of the new technology is the ability to perform additional testing, such as human papillomavirus (HPV) determination on the same sample (see Chap. 11). A major disadvantage is the introduction of artifacts such as cell shrinkage and modified staining properties requiring new training and experience. Until then, as stated by Austin (1998), "for now, it still may be premature to declare the Pap smear the most successful and proven cancer screening test in medical history, as 'inefficient' and 'the problem' while characterizing a less-tested new method amid Shakespearean overtones as 'potent', 'the promise' and 'the hope'."

PROCESSING OF FLUID SPECIMENS

Preservation of Material

Preservation of cellular morphology until the sample can be processed is essential to accurate cytologic interpretation. For the purpose of this discussion, "prefixation" refers to the collection of a fluid specimen in a medium that will preserve morphology up to the time of slide preparation. A "fresh sample" is one to which no fixative or preservative has been added.

Fresh Material

Specimens may be submitted to the laboratory without preservative if facilities for immediate processing are available. The length of time between collection and preparation of the sample before cellular damages occur depends on pH, protein content, enzymatic activity, and the presence or absence of bacteria. It is not possible to predict these variables, even in specimens from the same anatomic site. However, the following guidelines will usually yield acceptable results.

P.1575

- **Specimens with a high mucus content**, such as sputums, bronchial aspirates, or mucocoe fluid, may be preserved for 12 to 24 hours, if refrigerated. Refrigeration slows the bacterial growth that causes cellular damage and the breakdown of mucus. Mucus apparently coats the cells, protecting them against rapid degeneration. The cells in specimens without thick mucus or specimens diluted with saliva are not as well protected and may deteriorate more rapidly.
- **Specimens with a high protein content**, such as pleural, peritoneal, or pericardial fluids, may be preserved for 24 to 48 hours without refrigeration. The protein-rich fluid in which the cells are bathed acts as a tissue culture medium in preserving cellular morphology.
- **Specimens with low mucus or protein content**, such as urine or cerebrospinal fluid, will endure only a 1 to 2-hour delay, even if refrigerated. The fluid medium in which these cells are bathed contains enzymatic agents capable of causing cell destruction. Refrigeration may inhibit bacterial growth but does not protect the cells.
- **Specimens with low pH**, such as gastric material, must be collected on ice and be prepared within minutes of collection to prevent cellular destruction by hydrochloric acid.

Prefixation of Material

Prefixation may preserve some specimens for days without deterioration of cells. Some of the disadvantages of prefixation are precipitation of protein, hardening of cells in spherical shapes, and condensation of chromatin. The most common solutions used for this purpose are discussed below.

- **Ethyl alcohol (ethanol) [50% solution]** was once considered the best universal fixative for fluid specimens. Its effectiveness as a preservative, particularly of urine samples, has come under scrutiny (Crabtree and Murphy, 1980). Pearson et al (1981) reported that the morphologic features of urothelial cells, suspended in urine at a pH of 4.5, were better preserved than in other samples, regardless of whether or not ethanol was added. The addition of methanol, however, improved preservation of detail in samples of pH higher than 4.5. This same study also found the pH of the first morning voiding to be lower than that of subsequent ones and that 1g of vitamin C, taken the night before sample collection, significantly reduced the pH. However, if one opts to use it as a preservative, ethanol should be added in equal volume to the fluid. **Ethyl alcohol in a concentration higher than 50% should not be used in collecting fluids rich in protein**, because the sediment becomes hardened and very difficult to spread on glass slides, particularly if the delay in processing is greater than 1 hour. However, 95% ethyl alcohol may be effectively used in the collection of gastric washings. **Fixatives containing ether or acetone should never be used for liquid specimens that cannot be smeared on slides immediately after collection.** Hardening of the sediment makes the subsequent preparation of smears almost impossible.
- **Saccomanno's fixative**. Samples can be collected directly into the Saccomanno's fixative or the fixative can be added to the sample once it arrives in the laboratory. When used as a prefixative, it is generally recommended that it be added in equal volume to the specimen. See above for this method of preparation and additional uses.
- **Shandon Mucollex** is a commercial, mucoliquefying preservative designed for use in the collection of mucooid and fluid specimens. Its active ingredients were polyethylene glycol, methanol, buffering agents, and aromatics. An equal volume of undiluted Shandon Mucollex

added to the specimen was recommended by the manufacturer (www.Thermo.com, Product #9990370). A similar product called Mucolytic Agent (Stephens Scientific, Riverdale, NJ) is available (catalog no. S7744).

- **Commercial preservatives**, such as Cytospin Collection Fluid (Thermo Electron Corporation, Pittsburgh, PA, www.thermo.com), are also available.
- *Many other preservatives have been developed for use with automated cytology systems* that may have practical application for routine cytology. Weidmann et al (1997) tested CytoRich Red, a proprietary formula of buffering agents, emulsifiers, formaldehyde, and alcohol developed for use with TriPath PREP (TriPath Imaging, Inc) for use as a preservative. CytoRich Red was added to a variety of nongynecologic specimens. The specimens were kept for up to seven days before preparation of slides, using the Cytospin III (www.Thermo.com) and the Hettich Universal cytocentrifuge. There was a marked reduction of erythrocytes and background material, when compared to slides prepared from the same specimens collected in Cytospin Collection Fluid (www.Thermo.com). Table 44-3 summarizes the use of the preservatives described.

Comment

The decision to prepare slides from fresh or prefixed material is influenced by the number of specimens processed by the laboratory, the number of trained personnel available to prepare the material, and the cooperation of the physicians and nursing staff involved in collection of samples. We do not recommend one method in preference to another but believe that consistency is important. For example, if sputum or urine samples are routinely collected in 50% ethanol, unfixed samples should be fixed immediately upon arrival in the laboratory to ensure uniformly consistent cytologic artifacts for microscopic evaluation.

PREPARATION OF FLUIDS FOR MICROSCOPIC EXAMINATION

Many papers have been published comparing the diagnostic accuracy of different preparation techniques. Often, the results of these studies contradict one another. A detailed discussion of the advantages and disadvantages of each method is not possible in this chapter. As with collection techniques, the methods used for preparing specimens will vary according

P.1576

to the volume of specimens processed, personnel available, and collection techniques. The most commonly used procedures can be divided into the following categories:

TABLE 44-3 DIRECTIONS FOR USE OF SEVERAL FIXATIVES		
Preservative	Specimen	Instructions
50% ethanol Saccommanno Mucollex	All body sites except gastric	Sputums: Have the patient expectorate directly into cups containing 50 ml of preservative and shake well. Other specimens: add an equal volume of preservative and mix well.
70% ethanol		
95% ethanol		

- **Direct or sediment smears on glass slides**
- **Cytocentrifuge preparations**
- **Automated cytology systems**

- **Preparation with membrane filters**
- **Preparation of cell blocks**

Materials required:

- Petri dishes and brown paper toweling
- Curets, applicator sticks, forceps, or similar instruments. The nasal curet shown in Fig. 44-1 is one such instrument that can be easily rinsed in a germicidal solution and flamed after each specimen.
- Copper paper clips for keeping the slides separated from each other in the fixative.
- Glass slides. Slides should be 0.95 to 1.06 mm in thickness to ensure good microscopic illumination. Slides may be plain, albuminized, or coated with another adhesive (see below) and can be labeled permanently with a diamond-point pencil or black laboratory ink. A lead pencil (No. 3 hardness) can be used for temporary identification of slides with frosted ends. Permanent paper labels can be applied after coverslipping. The choice of plain, albuminized, or adhesive-coated slides will depend on the mucus content of the material to be smeared. **Totally frosted slides should not be used as** they distort the cells on smearing.
- Bottles of 95% ethyl alcohol or equivalent (see Table 44-1).
- Centrifuge tubes: 50-ml capacity, preferably disposable plastic tubes with a screw cap
- Centrifuge: 50-ml tube capacity with a horizontal head. Cell fractionation studies have shown that cells sediment best at $600 \times$ gravity in 10 minutes. To determine the centrifuge speed or revolutions per minute (rpm) required to equal $600 \times$ gravity for an individual centrifuge:

Measure the radius of the centrifuge from the center pin of the rotating head to the end of the extended cup (Fig. 44-2).

Place a straight edge on the chart in Fig. 44-3 intersecting the rotating radius and 600 gravities. The point at which the straight edge intersects the speed scale is the recommended rpm.

Figure 44-1 A small curet-type spoon successfully used in this laboratory for transferring sediment from centrifuge tube or sputum to slide.

Preparation of Direct or Sediment Smears on Glass Slides

Specimens consisting of a small amount of material that adheres well to glass slides (e.g., cervical scrapes, brushing, needle aspirates) can be smeared directly on a slide, using a steady motion (see Chap. 28 for further comments on smear preparation techniques).

Coating Glass Slides With Adhesives

In order to optimize the adhesion of cells to the surface of the glass slide, coating adhesives can be used. They can also be prepared in the laboratory.

Mayer's Albumin

Mayer's albumin is available commercially or can be prepared in the laboratory as follows: Mix by stirring 1 volume

P.1577

of fresh egg whites or reconstituted dried egg albumin (1 g of albumin per 20 ml of distilled water) with an equal volume of pure glycerol. Filter this mixture through damp muslin or coarse filter paper in an oven (55° - 58° C). Add a few crystals of thymol or camphor to prevent growth of molds. Store this solution in small screw-capped bottles at a temperature of -4° C. The bottle of albumin currently in use must be refrigerated.

Figure 44-2 Determination of the rotating radius of the centrifuge.

Figure 44-3 Chart to be used for the determination of centrifuge speed (revolutions per minute) at gravity 600. The scale on the left shows the length of the rotating radius in centimeters or inches. The central scale shows relative centrifugal force or gravities. The right scale shows centrifuge speed expressed as revolutions per minute. In the example given, a straight line intersects the rotating radius at 25 cm, or approximately 10 inches (A), and the centrifugal force at 600 gravity (B). An extension of this line shows 1,500 as the number of revolutions per minute for optimal centrifugation (C).

Albuminized slides should be prepared one to several days before use to allow the slides to become tacky. Arrange the slides on a clean tray and, using a dropper, place a drop of Mayer's albumin on each one. With the fingertip covered

P.1578

by a thin rubber cot, spread the albumin thinly and evenly over the entire slide, or lay another slide on top, rubbing the two slides together to obtain uniformly coated slides. Keep the coated slides in a dustproof area of the laboratory, in a closed slide box, or cover with wax paper.

Gelatin Chrome Alum

The adhesive *gelatin chrome alum* is superior to albumin for transferring cells from membrane

filters to glass slides; it may also be of use for routine slide preparation of poorly adhesive samples. As described by Adler (1978), the adhesive consists of 1 g of gelatin plus 0.1 g of chrome alum dissolved in 100 ml of distilled water, to which 1 ml of 10% thymol in ethanol has been added. Slides are dipped once, drained, their backs wiped off, and then allowed to dry. Slides are stored, as previously described, for albuminized slides. They may be stored for weeks. However, maximal cell adhesion has been reported if the solution is prepared one day prior to use.

Poly-L-Lysine

Poly-L-lysine is a potent cell adhesive that is particularly useful in experimental work (scanning electron microscopy) and in immunocytochemistry (Domagala et al, 1979, Huang et al, 1983).

A 0.1% stock solution of poly-L-lysine in deionized water (molecular weight 380,000) is commercially available from Sigma Diagnostics (Sigma-Aldrich Co., St. Louis, MO, www.sigmaaldrich.com; catalog no. P8920). The stock solution is diluted 1:10 or 1:100 in deionized water. Clean glass slides are placed in the diluted solution at room temperature for 5 minutes and are oven-dried. Dried slides are ready to use. The coated slides significantly improve adhesion of cells and tissues. Poly-L-lysine is easy to use and can be used as a universal coating agent.

3-Aminopropyltriethoxysilane (3-APTES)

Another excellent adhesive is *3-aminopropyltriethoxysilane* (3-APTES), also from Sigma Diagnostics (www.sigmaaldrich.com, catalog no. A3648). The compound adheres to glass and binds to cell surface. A 2% solution of 3-APTES in acetone is prepared. The solution may be used to coat clean slides, as described above, but may also be used to better attach cells and tissues to slides in archival material (Rule et al, 1989). We successfully used this compound in an in situ hybridization procedure of archival cervical smears with DNA biotinylated probes of human papillomavirus (Liang et al, 1991).

Shaklee Basic H and Surgipath Sta-on

Johnson et al (2000) developed a solution that simultaneously cleans the slides and coats them with a uniform layer of adhesive at a fraction of the cost of commercial adhesives. It uses a 1:9 mixture of Shaklee Basic H and Surgipath Sta-On. A stock solution with a shelf life of at least 1 year is prepared by mixing 10 cc Shaklee Basic H (Shaklee Corporation, Pleasanton, CA) with 90 cc Surgipath Sta-On (www.Surgipath.com, catalog nos. 03105 and 03107). The working solution, which is good for 1 week, consists of 20 cc of stock solution and 480 cc deionized water. Slides are dipped in the solution and air-dried.

Processing of Sputum, Bronchial Aspirates, and Other Mucus-Rich Samples

Mucoid samples present unique challenges. Concentration of cells by centrifugation is not possible because of high viscosity. To increase diagnostic yield, alternative methods, such as the "pick and smear" technique, Saccomanno's technique (mechanical homogenization), and a variety of chemical homogenization procedures, have been developed.

A variety of methods using DTT homogenization (see below) seem economical, simple and easily adaptable for routine processing. One such method is described as follows.

Dithiothreitol (DTT) Mucus Liquefaction

- DTT Solution: 0.2% DTT (www.sigmaaldrich.com, catalog no. D0632) in 60% ethanol and 3% Carbowax.
- If the sample is **fresh**: add twice the volume of DTT solution. For example, to 5 cc of sputum, add 10 cc of DTT. Thoroughly agitate sample with a vortex mixer. Let stand at room temperature for 30-60 minutes vortexing periodically. Centrifuge sample, prepare slides by the method of your choice, allow slides to air dry, and stain as usual.
- If sample is **fixed**: Centrifuge sample, pour off supernatant and prepare as described above.

"Pick and Smear" Technique of Sputum Processing

This technique is applicable to fresh samples or samples prefixed in 50% alcohol (Fig. 44-4). The selection of bloody or solid particles is critical in correct processing of sputum. To select such particles, the sputum must be carefully inspected. This may be done by pouring the specimen into a Petri dish and examining it against a black background. Excellent results may be obtained by pouring sputum specimens on two or three thicknesses of brown paper toweling. The paper toweling absorbs most of the fluid portion of the specimen and allows the selection of particles. Sputum is often difficult to transfer to slides in small amounts because of

its viscous, ropy consistency. The use of two specially-designed curet-type instruments, nasal curets (see Fig. 44-1), or applicator sticks, one in each hand, is required.

- Select any bloody, discolored, or solid particles, if present, and place a small portion of each particle, not larger than the size of a small pea, on each of four plain slides. With a clean glass slide, crush the particle of sputum on each of the four slides, using a rotary motion. Then, with overlapping horizontal strokes, spread the material evenly over the slide so that the final preparation is only slightly thicker than a blood smear. *Place the prepared slides immediately in a Coplin jar with 95% ethyl alcohol fixative, or its equivalent* (see Table 44-1), making sure that the smeared surfaces remain separated by paper clips. In the absence of particles, sputum samples from

P.1579

at least four different portions of the specimen must be smeared.

- If cell blocks are to be prepared, save the part of the specimen remaining after preparation of smears and proceed as outlined below.

Figure 44-4 Diagrammatic representation of steps in the preparation of smears from sputum.

Tang et al (1995) compared the sensitivity of the "pick and smear" method to the homogenization of the specimen with Dithiothreitol (DTT) (www.sigmaaldrich.com, catalog no. D0632). In their study, the relative sensitivity of detecting positive cases by the DTT method was 98.8% compared with 80.0% by the "pick and smear" method, a statistically significant difference in detection rates.

Saccomanno's Technique

- To a sputum specimen received in Saccomanno's fixative (Fig. 44-5), described above, add sufficient Saccomanno's fixative to make a total volume of 50 ml. If specimen is received in 50% alcohol, add a sufficient amount of Saccomanno's stock solution to achieve a final concentration of approximately 2% Carbowax; for example, to 45 to 50 ml of specimen, add 4 ml of Saccomanno's stock solution and mix well. Specimen should remain in this fixative approximately a half hour before processing.
- Pour the specimen into a semi-micro container (Cardinal Health, www.cardinal.com; Container, Semi-Micro Stainless Steel, Eberbach, catalog no. S8395-1) and blend in a Waring Blender (Cardinal Health, www.cardinal.com; Stirrer, Blender, 2 speed, Waring, catalog no. S8346-1) at high speed for 5 to 10 seconds. Container should remain capped during blending. If one prefers, blending can be avoided by adding a mucolytic agent, such as Sputolysin (Caldon Biotech, Inc, Carlsbad, CA) or Dithiothreitol (DTT) to the fixed specimen. Further processing of the sample is the same for blended or not blended specimens.
- Pour blended specimen into a 50-ml test tube. If flecks and fine threads are still visible, return to blender for an additional 5 to 10 seconds. Cells are not damaged unless specimen is blended excessively.
- Centrifuge specimen for 10 minutes at rpm determined for your centrifuge (see above). Decant supernatant, leaving a few drops of fluid to mix with the granular, pale sediment. Resuspend sediment by agitating the tube on a vortex mixer (Cardinal Health, www.cardinal.com; Maxi Mix Plus Mixer, catalog no. S8248-6).
- Prepare smears by placing a few drops of the resuspended sediment in the center of a clean slide. The number of drops depends on the consistency of the sediment: use only one to two

drops if the sediment is thick; use two to four drops if the sediment is thin and watery. Place a second, clean slide over the material and allow it to spread evenly between the two slides. Gently pull the slides apart with an easy sliding motion.

- Allow slides to air-dry until ready for staining. Smears may be stored for months in this condition without adverse effects. *As with coating fixatives, the slides should be rinsed in 95% alcohol for at least 10 minutes before staining to remove the Carbowax.* Failure to rinse the slides properly will impede the stain's penetration of the cell, alter the staining results, and contaminate the staining solutions.
- We have found it useful to use three semi-micro containers on rotating bases. After the first specimen is blended and poured into a centrifuge tube, the semi-micro container is filled with a 1:10 dilution of household bleach (sodium hypochlorite) for cleaning purposes and allowed to stand while the second container is being used for the next specimen. The second container is used and then filled with bleach while the first container is emptied of bleach and placed under a faucet of hot running water. The third container is used for the third specimen and filled with bleach while the second container is put under running water and the first container is ready to use again. Many laboratories use only one container and just rinse it well under running water between samples.

Figure 44-5 Sputum preparation after Saccomanno.

P.1581

Precautions

Harris, in a letter to the editor (1977), quotes a personal communication dated September 28, 1976, from J.E. Forney, Bureau of Laboratories, Centers for Disease Control, Atlanta, Georgia:

[T]he household blender has been shown to be one of the most hazardous pieces of equipment used in the laboratory in terms of production of potentially infectious aerosols. The blending step should be carried out in a safety-type blender which has been properly checked and maintained to prevent any leakage. Even when using the safety-type blender container, it should not be opened for at least one hour after the blending operation has been completed, because it takes that long for the infectious aerosols to settle in the atmosphere within the blender jar. The alternative would be to place the blender in a negative pressure cabinet which has an airflow velocity across the face of the cabinet of at least 75 linear feet per minute.

Saccomanno stated in a letter to the editor (1977):

[W]e have not experienced any infection in our laboratory utilizing this technique on over 125,000 specimens. We are aware that our area is not endemic for tuberculosis or fungal diseases. Also, we have added 3 mg of **Rifampin** to each fixative bottle with the understanding that this may be helpful and that a similar amount can be added to the specimen on arrival in the laboratory before preparation. Finally, a negative pressure hood should be used when possible.

Saccomanno (personal communication, August 1990) believes that blending pulmonary secretions poses no undue risk of exposure to the AIDS virus. His laboratory continues to blend samples under a negative-pressure hood, and his technologists wear gloves during the

procedure (see below for a discussion of universal precautions).

Preparation of Rifampin Solution

- Empty the contents of a 300-mg capsule of Rifampin (Rifadin, Aventis Pharmaceuticals, or Rimactane, CIBA Pharmaceutical Company, Division of Novartis, Summit, NJ) into 100 ml of 50% ethyl alcohol and blend at high speed in Waring blender. One ml of Rifampin solution should be added to each 50 ml of fixative just before it leaves the laboratory for distribution to patients or hospital wards.
- As an added precaution, add another milliliter of Rifampin solution to each specimen of sputum returned to the laboratory and let stand for 24 hours before processing.

Molecular Analysis of Sputum Samples

To determine the method best suited for use with polymerase chain reaction (PCR), Tockman et al (1995) compared the efficacy of mucus liquefaction with a variety of chemicals to the mechanical blending utilized by Saccomanno's technique. Using samples with known cell counts, the study showed a widespread loss of cells after mechanical mucolysis with a blender whereas there was an increase over baseline in cellularity of chemically homogenized samples. DTT was the most effective of the mucolytic chemicals studied. Homogenization with low-concentration DTT produced mucus-free monolayers, without background staining suitable for immunocytochemistry and single cell suspensions suitable for flow cytometry.

Pleural, Peritoneal Effusions, and Other High-Protein Fluids

Fresh Specimens

1. Pour specimen into 50-ml centrifuge tubes with screw cap and centrifuge for 10 minutes at recommended (usually 600) rpm (Fig. 44-6).
2. Pour off the supernatant. If there is only a small cell button, the tube should be inverted on paper toweling or gauze and allowed to stand until it is well drained. This prevents dilution of the sediment with the supernatant that runs down the sides of the tube. However, watch closely to prevent loss of the cell button on the paper toweling. Excess protein and blood coating the cells can interfere with the staining reaction. Washing the sediment once or twice with a balanced salt solution at this point will markedly improve the quality of the stain. If the sample is very bloody, the centrifugation may produce a buffy coat containing leukocytes and mesothelial and tumor cells, which may be observed above the layer of red blood cells. In order not to disturb the buffy coat, a Pasteur pipette can be used to remove all the supernatant. Under these circumstances, direct smears of the buffy coat may be obtained with excellent concentration of cells (see below for other methods for dealing with bloody fluids).
3. Transfer the sediment or buffy coat to a clean glass slide. Most well-drained sediments adhere well to clean slides; however, **albuminized slides** may be used. The following two methods are most frequently used for preparation of slides.
 - A. Place one to two drops of sediment on a slide by means of a disposable glass pipette or an instrument such as a nasal curet (see Fig. 44-1). Place a second clean slide over the sediment and allow it to spread evenly between the two slides. Gently pull slides apart with an easy sliding motion. *Fix immediately* by dropping slides into 95% ethyl alcohol or its equivalent (see Table 44-1). Uneven cell distribution ("ribbing effect") will occur if a smooth continuous motion is not used when immersing the slides in alcohol.
 - B. Use a bacteriology wire loop to remove the sediment. Move the loop quickly in a longitudinal, then horizontal direction over the surface of the slide. Immediately fix slide as described above.

Clotted Specimens

Fluids high in protein or bloody fluids that were not collected in an anticoagulant may form clots. Clots may be gently twisted or pressed against the side of the container by means of a wooden stick to wring out the fluid and trapped cells. The fluid should be processed as described above and the remaining clot processed as a cell block.

P.1582

Figure 44-6 Preparation of smears from body fluids.

P.1583

Bloody Fluids

Smears may be prepared as described for fresh specimens. However, erythrocytes may obscure the epithelial cells on smears made from excessively bloody fluids. It is also difficult to concentrate the epithelial cell component in such fluids.

Several methods are available for handling bloody samples, such as flotation techniques to separate the erythrocytes from other cellular elements (see below): hemolyzing the erythrocytes before slide preparation, lysing them after slide preparation, and lysing them after the slide has been stained.

Methods of Erythrocyte Lysis Prior to Slide Preparation

Lysing erythrocytes prior to slide preparation results in smears that are easier to interpret because of better recovery of epithelial cells. Older methods of erythrocyte hemolysis include addition of one of the following to 50 ml of sample: 1 ml of glacial acetic acid, or a few drops of a special hemolyzing agent such as **Lyse III** used with the Coulter counter, or 0.1 normal HC1 until a uniformly brown color appears. Unfortunately, the older techniques may cause unacceptable changes in morphology of cells.

Newer methods, using proprietary commercial agents, developed for use with automated cytology systems, are now available. These agents not only lyse the red blood cells but also fix the other cellular elements. Two such fixatives are **CytoRich Red** (Tripath Imaging, Inc., Burlington, NC) and **CytoLyte Solution** (Cytoc Corporation, Marlborough, MA). Workers have recommended adding as little as 1 ml of fixative per 25-50 ml of sample. Some recommend equal volumes of fixative and sample. After letting the mixture sit for a few minutes, the sample is centrifuged, the supernatant poured off, and slides prepared by the usual method used in the laboratory. Alternatively, the solution can be added to the bloody sediment after centrifugation and the sample re-centrifuged after lysis of the erythrocytes.

Method of Erythrocyte Hemolysis after Slide Preparation

Weidman et al (1999) recommend the use of CytoRich Red Fixative (TriPath Imaging, Inc, Burlington, NC) for lysing erythrocytes on a bloody smear. The method involves immediately dropping the bloody smear into **CytoRich Red** just as if one were fixing it in ethanol. After 30 seconds, the slide is transferred to 95% ethanol and processed as usual. When compared to simultaneously prepared bloody smears not treated with CytoRich Red, there was no appreciable cell loss and the staining characteristics of cells were not altered.

Pieslor et al (1979) recommend the following method, which is suitable for both stained and unstained slides. The hemolyzing agent is a **2M urea solution** that can be prepared by dissolving 120 g of powdered urea (JT Baker Chemical Co, Phillipsburg, NJ) in 1 liter of distilled water. After a minimum 5 minutes of fixation in 95% ethanol, bloody smears are placed in a Coplin jar containing the urea solution for 20 to 30 seconds, then transferred back to the ethanol fixative and stained routinely. To lyse cells from stained slides, remove coverslip and take slides back through xylene and alcohol to water. Place slide in urea for 5 to 10 minutes,

transfer to 95% alcohol, and then restain slide with routine stain.

Carnoy's fixative can also be used to lyse erythrocytes before and after a slide has been stained (see above).

Prefixed Fluids

Prepare slides as described under fresh specimens; however, the **use of albuminized or adhesive-coated slides is essential**.

Bronchial, Gastric, and Other Washings Collected in Normal Saline Solution

1. Pour washings into 50-ml plastic screw-cap centrifuge tubes and centrifuge for 10 minutes at predetermined (usually 600) rpm.
2. Pour off supernatant. If the sediment is very mucoid, smears may be prepared as described for sputums and bronchial aspirates (see Fig. 44-4). Sediment that contains only a small amount of mucus can be prepared by the two-slide pull method described for high-protein fluids (see Fig. 44-6). If the sediment has no visible mucus, it should be prepared as described for urine sediment (see below). The Saccomanno technique may be used by centrifuging the washing for 10 minutes at the proper rpm, discarding the supernatant, adding 50 ml of Saccomanno's fixative to the sediment, and letting it stand for 2 hours. The slides are then hand-prepared as described in steps 2 through 7 of the Saccomanno technique for sputums (see above). If the bronchial washing is collected in Saccomanno's fixative, steps 1 through 7 of the same procedure may be used.

Urine, Cerebrospinal Fluid, and Other Protein-Poor Fluids

A variety of methods has been developed to deal with the unique characteristics of fluids with low cellularity and low protein content. Cytocentrifuge preparations, membrane filters, Leif buckets, and direct smears from the sediment yield adequate preparations, if specimens are handled with care. In our laboratory, a combination of cytocentrifuge and direct smears of the sediment is used. Prevention of cell loss and satisfactory preservation of morphologic detail are the two goals of the procedure. Cell loss may be substantial if slides are wet fixed in alcohol. Beyer-Boon and Voorn-den Hollander (1978) estimated the loss to be from 74% to 98%. With the semi-automated technique developed in this laboratory (Bales, 1981), the cytocentrifuge preparations using Shandon Cytospin I (Thermo Electron Corporation) resulted in cell-rich monolayer preparations of excellent morphologic quality. **The Bales method is applicable to urine, cerebrospinal fluid, and other specimens with a low cell and protein content.** Likewise, the smears made directly from the sediment are generally rich in cells and exhibit outstanding cellular detail.

P.1584

Figure 44-7 Bales' method of preparation of voided urine sediment for cytologic examination (see Figs. 44-8 and 44-9).

Bales Method (*Acta Cytol* 25: 895-899, 1981)

Materials required:

1. Carbowax 1540
2. Ethanol (95% solution)
3. Oxford Series P-700 Micropipetting with one pipette each of capacities 3 μ l, 50 μ l, and 200 μ l

and plastic disposable tips suitable for the system chosen

4. Repipet dispenser of 1-ml capacity
5. Repipet dispenser of 5-ml capacity
6. Maxi Mix Plus Mixer (Fisher Scientific, catalog 12-815-18, www.Fishersci.com)
7. Plastic test tubes of 50-ml capacity
8. Clean glass slides

Preparation of Carbowax Stock Solution

Carbowax 1540 is solid at room temperature, with a melting point of 43° to 46°C. To avoid the necessity of melting it whenever the fixative is needed, a stock solution of Carbowax can be prepared as follows. Pour 500 ml of water into a 1,000 ml graduated cylinder. Melt the Carbowax in an incubator or hot-air oven at 50° to 100°C. Add 500 ml of the melted Carbowax to the graduated cylinder. This mixture will not solidify and can be stored in a liter screw cap bottle.

Preparation of 2% Carbowax Solution in 70% Ethanol

A liter of 2% Carbowax fixative in 70% ethanol is prepared by mixing 223 ml of water, 737 ml of 95% ethyl alcohol, and 40 ml of the water-based stock solution of Carbowax.

Preliminary Preparation of Sample

The preliminary preparation of a sample is carried out in the following steps (Fig. 44-7), using fresh urine or urine prefixed in an equal volume of 50% ethanol:

1. Centrifuge 50 ml of the sample for 10 minutes at 600 g.
2. Pour off the supernatant and invert the centrifuge tube on paper toweling to drain the sediment well.
3. Using a Vortex mixer, briefly agitate the well-drained sediment.
4. Proceed to cytocentrifuge or smear preparations as desired.

Preparation of Cytocentrifuge Slides*

To prepare slides by cytocentrifugation, use the following steps (Fig. 44-8):

1. Aspirate precisely 3 µl of the sediment obtained in the preliminary preparation of the sample.
2. Expel the sediment into a test tube containing 400 µl of 2% solution of Carbowax into alcohol (Test tubes can be filled in advance using a repipette set to dispense 400 µl of fixative. These tubes must be stored in the refrigerator until needed).
3. Briefly agitate the mixture on a Vortex mixer to prevent formation of cell aggregates.
4. Aspirate 200 µl with an automatic pipette and place in a cytocentrifuge chamber.
5. Repeat step 4 and place the remaining 200 µl in the opposed cytocentrifuge chamber.
6. Spin for 5 minutes, remove slides, and allow them to air-dry for 10 to 30 minutes in a dust-free environment.
7. Rinse slides in 95% alcohol for 10 minutes prior to staining.

P.1585

Figure 44-8 Bales' method of preparation of voided urine sediment for cytologic examination by cytocentrifugation (see Figs. 44-7 and 44-9).

Preparation of Smears

Smears may be prepared from the sediment as follows (Fig. 44-9):

1. Add 3 to 5 ml of the 2% Carbowax solution to the sediment obtained in the preliminary preparation of the sample and agitate on a Vortex mixer.
2. Let stand in a vertical position for 10 minutes and, thereafter, centrifuge at 600 g for 10 minutes.
3. Pour off the supernatant and drain the sediment as described in step 3 of the preliminary preparation of sample. Agitate the sediment on the Vortex mixer.
4. Aspirate 50 μ l of the sediment by means of an automatic pipette and place on a clean glass slide. Lay second clean slide on top of the sediment and let the sediment spread spontaneously between the two slides. Pull the slides apart with a gentle gliding motion. Place the two slides with the gray sediment face up and let them air-dry for 10 to 30 minutes in a dust-free location. Rinse the dry slides for 10 minutes in 95% ethanol prior to staining.

Results

Cell-rich, yet flat, monolayer cytocentrifuge preparations of urine and cerebrospinal fluid were routinely obtained by the use of this method. The epithelial cells, whether benign or malignant, were exceptionally well preserved. There was virtually no overlapping of cells. Minimal drying artifacts were occasionally observed in polymorphonuclear leukocytes. The method provided sufficient detail for it to be used routinely in image analysis of sediments of voided urine with excellent results (Koss et al, 1984, 1985, 1987; Sherman et al, 1986). Examples of the results are shown in Chapters 22 and 23. Equally good results were obtained in cerebrospinal fluid (see Chap. 27).

The method is highly recommended and can be executed by technical personnel with minimal training and experience.

CYTOCENTRIFUGATION

A cytocentrifuge is a device that spins cells in a fluid suspension directly onto a glass slide. Since the introduction of the Cytospin I by Thermo Electron Corporation, other instruments have been developed with slightly different features. Following the guidelines and procedures recommended by the manufacturer of the instrument usually results in excellent cytologic material.

Cytocentrifuges

Shandon Cytospin II and III

Newer Cytospin models (Thermo Electron Corporation, www.thermo.com) have features that increase cell recovery. The Cytospin II and III form an air bubble between the sample and the slide which increased cell recovery rates when compared to the Cytospin I. Also available is a

Megafunnel for use with the Cytospin II or III, which allows the processing of up to 12 times the sample volume (6 ml) and

P.1586

deposits the cells over an area 10 times larger than the cell deposition area of Cytofunnel. The Megafunnel is designed for highly cellular samples such as effusions, bronchial washings and sputums.

Figure 44-9 Bales' method of preparation of smear of voided urine sediment for cytologic examination (see Figs. 44-7 and 44-8).

Wescor Cytopro

Wescor Cytopro (Wescor, Inc, Logan, UT) is an economical, easy to use, 8-chamber, stand-alone cytocentrifuge. Wescor also has an automated cytology slide stainer that can deliver 160 stained slides per hour. Since each slide is stained individually, there is no possibility of cross contamination and no filtering of reagents is necessary. This stainer can be converted to a cytocentrifuge by adding the Cytopro rotor.

Hettich Cytocentrifuge

The Hettich Cytocentrifuge (Andreas Hettich Co, Tuttlingen, Germany) has 8 ml chambers that resemble a flat bottom test tube. It deposits cells on the slide in a circle 17.5 mm in diameter. Because of its comparatively low cost, ease of operation and reusable chambers, some workers recommend this instrument for liquid-based gynecologic cytology as well as for nongynecologic material.

Leif's Centrifugal Cytology Buckets

An excellent method that, unfortunately, never received wide acceptance, was a bucket method wherein cells suspended in small amounts of fluid, for example, in cerebrospinal fluid, could be spun directly onto glass slides. The method was developed by Leif (1975) and was marketed by Coulter Electronics (Coulter Electronics, Inc., Hialeah, FL [now Beckman Coulter, Fullerton, CA]). The 8-chamber bucket, which can be adapted with almost any laboratory centrifuge, allows simultaneous processing of three samples. The manufacturer provides detailed guidance on the use of the bucket. This author has no personal experience with the method; however, review of slides prepared in this manner exhibited excellent cytologic detail with uniform cell distribution. The cells are wet-fixed during centrifugation, thereby avoiding air-drying artifacts.

Optimal Use of a Cytocentrifuge

Major objections to the use of the cytocentrifuge include distortion of cellular morphology due to air-drying artifact and loss of cells by absorption of fluid into the filter card. Both of these difficulties have been overcome with the newer techniques described. The rare drying artifact of polymorphonuclear leukocytes rarely affects epithelial cells; hence, the diagnostic value of the preparation is not reduced. During the developmental stages of the Bales Method, the quantification of sediment necessary to achieve a monolayer cytocentrifuge preparation was studied by flow cytometry. The particle counts obtained in this manner proved to be of no assistance in achieving the goal. After considerable trial and error, it was determined that the volume of sediment, rather than the particle count, was crucial to achieving cytocentrifuge

preparations with minimal overlap of cells and satisfactory morphologic characteristics. The precise amount of sediment (3 μ l) obtained by means of an automated calibrated pipette has consistently resulted in monolayer cytocentrifuge preparations. Our procedure was developed using the Cytospin I. In 1981, Shandon introduced the Cytospin II with slightly different features, one of which is the automatic

P.1587

formation of an air bubble between the cell suspension and the slide. Recovery rates from the Cytospin II were consistently twice as high as those with the Cytospin I (Boon et al, 1983). When, however, the air bubble was deliberately introduced into the chambers of Cytospin I, the recovery rates were similar.

Because of the increased cell recovery with newer model centrifuges, the volume of sediment must be reduced in order to achieve a monolayer. We recommend experimenting with different volumes of sediment to determine the optimal volume needed to produce a monolayer for the cytocentrifuge used in your laboratory.

Not only is the volume of sediment critical to producing a monolayer of cells, but the amount of diluent is important. Grover, Blee, and Stokes (1995) compared cell recovery using the Wescor Cytopro (Wescor, Inc, Logan, UT) and Shandon Cytocentrifuge II (www.thermo.com). Fixed cell numbers were suspended in varying amounts of diluent so that, regardless of the amount of fluid placed in the chamber, the number of cells per chamber remained the same.

As the volume of fluid increased, the fractional recovery of cells increased from 10% to 100%. The distribution of cells on the slide also improved with the higher volume of fluid. Deposition of the cells at the periphery (bull's-eye effect) was eliminated as fluid volume increased.

The sample volume required per chamber was between 200 to 500 μ l in both high and low cellularity samples. Whether re-suspending cells in a diluent or using unspun samples, it is important to bring the volume up to at least 200 μ l per chamber. In the case of low cellularity samples, such as cerebral spinal fluid, it is especially important, since one can ill afford the loss of cells.

Precaution: If reusable chambers are used after processing Carbowax-treated samples, the sample chamber should be washed thoroughly, not just soaked in a disinfectant. Chambers that are merely rinsed and allowed to dry, even after weeks of disuse, can contaminate other specimens with residual well-preserved cells from previous runs. Washing the chambers with a small brush or soaking them in bleach usually prevents this from occurring. Alternatively, the chambers can be sterilized with boiling water or autoclaved at a maximum temperature of 120°C, or they can be cleaned with a chemical sterilizing agent.

FILTERS

The use of membrane filters for the concentration of cancer cells suspended in fluid was introduced by the late Dr. Sam H. Seal of Memorial Sloan-Kettering Cancer Center. Gelman, Millipore, and Nuclepore, are the trade names of the most commonly used filters. Each filter has different physical, chemical, and optical properties and must be handled differently to obtain optimal results.

Gelman and Millipore filters are made of cellulose, are approximately 140 μ m thick, and are opaque white in appearance, until cleared in xylene and mounted in a mounting medium with a similar refractive index. The Nuclepore is a colorless, transparent membrane 10 μ m thick, made of polycarbonate. Rectangular sheets (19 \times 42 mm Millipore and Nuclepore, 17 \times 42 mm Gelman), 25-mm disks, and 47-mm disks that can be cut in half to make two slides, are available. The pore diameter most frequently used for cytologic preparation is 5 μ m.

The materials needed, specimen requirements, and method of filtration are essentially the same for all three types of filters. The major differences are related to staining and the mounting of the filters.

Materials needed:

1. Membrane filters
2. Filter holder to fit membrane to be used
3. Vacuum flask, tubing, and a three-way stopcock
4. Vacuum source with regulator and gauge
5. Forceps (nonserrated)
6. Balanced salt (electrolyte) solution, such as Hanks' balanced salt solution, or Abbot's Normosol. Normal saline solution is frequently used but is reported to cause **nuclear** and cytoplasmic distortion.

7. Petri dishes
8. 95% Ethyl alcohol
9. Ball-point pen with indelible ink

Specimen Requirements

For best results, the specimens should be collected fresh. Prefixation coagulates proteins that may clog the filters and harden the cells into spherical shapes, preventing flattening of the cells on the membrane's surface.

With the exception of urine specimens, small-volume and clear fluids may be filtered directly without prior centrifugation. Urine contains salts that are in solution at body temperature but that may precipitate when the urine cools to room temperature. Even though the urine appears grossly clear, these salts may clog the filters. Body cavity fluid specimens also contain debris and protein that may clog the filters. Therefore, urine samples, body cavity fluids, and other voluminous fluid samples should be centrifuged for 10 minutes at the recommended rpm; the supernatant is poured off; and the sediment resuspended in a balanced salt solution. Centrifuge this sample again and carefully pour off the supernatant. Once washed, cells do not adhere well to the centrifuge tube. Mix sediment with the small amount of balanced salt solution that runs down the side of the tube. The sample is now ready for filtration.

Mucoid specimens must be liquefied by use of a mucolytic agent, such as described above, or by blending as described in the Saccomanno technique. The specimen should then be centrifuged and washed as described above.

Filtration Procedures

1. Label Millipore and Gelman filters with indelible ink to identify patient and the cellular side of the filter (Fig. 44-10). Nuclepore filters may be marked with a hard lead pencil. If a 47-mm filter is used, the left and right sides should be labeled since the filter will be cut in half.

P.1588

2. Pre-expand Millipore and Gelman filters in a Petri dish filled with 95% ethyl alcohol for 10 to 15 seconds. This prevents wrinkling of the filter when refixed in alcohol. Moisten Nuclepore filters in a Petri dish filled with a balanced salt solution.
3. Moisten the grid of the filter setup with balanced salt solution. Using nonserrated forceps, lay the pre-expanded or premoistened filter on the grid, label side up.
4. Place the funnel on top of the filter. Do not clamp funnel to base. Add 15 to 20 ml of balanced salt solution to funnel and start the vacuum. The filter will be flattened by allowing a portion of the salt solution to pass through the filter. Stop the vacuum at this point and clamp the funnel to the grid.
5. Add 50 to 100 ml of balanced salt solution to the funnel. By means of a disposable pipette, add one to two drops of the sediment to the solution in the funnel.
6. Start vacuum (up to 100 mm of Hg for Millipore and Gelman filters and up to 20 mm of Hg for Nuclepore filters). As the specimen filters, add balanced salt solution from a squeeze bottle to rinse filter well. The stream of the squeeze bottle should be directed against the sides of the funnel to minimize aerosol sprays and to prevent disturbance of the cells on the surface of the filter. Stop the vacuum as soon as the flow of liquid begins to slow down. The filter should appear to be clean. Red blood cells will give the filter a reddish hue. To lyse these red blood cells, add a few milliliters of 50% ethanol. If the filter is not overloaded, it will change from red to white. If the filter appears clean, add more salt solution and restart vacuum until a small amount of solution remains. The surface of the filter should always be covered with fluid, and not merely moist or wet-looking. *Never permit the filter to dry.*
7. Add 20 to 30 ml of 95% ethanol to fix the cells in situ. After 1 minute, carefully restart the vacuum to pull the

P.1589

fixative through the filter. Stop the vacuum when a small amount of alcohol still remains to cover the filter.

8. Unclamp the funnel, remove the wet filter with a nonserrated forceps, and place the filter, cell side up, in a Petri dish with 95% ethanol. The filter is ready for staining after remaining in fixative for one-half hour (see below for special staining and mounting requirements).
9. Place funnel, forceps, and grid in disinfectant solution.

Figure 44-10 Method of filter preparation (for details see text).

Filters are excellent means of recovering cells from sparsely cellular specimens; however, we do not recommend their use for effusions. To ensure good cytomorphology, the limitations and advantages of the different filters must be understood. Careful attention to the chemical, physical, and optical properties of the filters will maximize their efficiency and minimize their limitations (Table 44-4).

The methods of staining, mounting, and dissolving filters are described below.

Methods of Transferring Cells From Filters to Glass Slides

Monolayer imprint smears can be prepared from filter preparations and stained as usual. Volet described a technique of transferring prefixed cells from filters to glass slides in 1965. The use of cold slides was essential to ensure good adhesion of the cells to the slide. A similar technique using frozen slides without any coating adhesive was described by Boccato in 1981. Sarkar and Kyriakos (1995) obtained excellent results by spraying the undersurface of slides kept at room temperature with a commercial cryofixative (Frostbite, Surgipath Medical Industries Inc, Richmond, IL), placing the filter cell side down and applying firm but gentle pressure to filter paper placed on top of the slide. The slide was immediately fixed in 95% ethyl alcohol. Cell loss was minimal and cells were deposited in a concentrated area within a clean background. Cell preservation and cytologic detail were excellent.

TABLE 44-4 EFFECTS OF VARIOUS COMMON CHEMICALS ON FILTERS

	Little or No Effect	Some Effect	May Dissolve or Deform
	Chloroform		
<i>Millipore Filter</i>	Formalin		Acetone
	100% Isopropanol	95% Ethanol: Swells	Methanol
	Xylene		100% Ethanol

Gelman Filter	100% 2-Propanol		
	Formalin		
	100% 2-Propanol		
	100% Isopropanol	95% Ethanol: Swells	Chloroform
	Xylene		Acetone
	100% Methanol		
Nuclepore Filter	100% Ethanol		
	Formalin		
	100% 2-Propanol		
	100% Isopropanol	Xylene: Curls if left longer than 10 to 15 min.	Chloroform
	100% Methanol		
	100% Ethanol		
	95% Ethanol		

Cyto-Tek MonoPrep Manual Filtration System

The Cyto-Tek MonoPrep (www.emsdiasum.com) is a simple liquid-based slide preparation method that does not require a major capital expense. The system consists of vials containing a preservative with mucolytic action, a syringe, a housing assembly with proprietary filter, and a fixative used for slide preparation. Specimens may be collected in the preservative or the preservative may be added to fresh samples in the laboratory. Fine needle aspirations performed by clinicians can be expelled into the preservative for transport to the laboratory. Briefly, the procedure consists of attaching the syringe housing the filter to the collection vial, pulling back the plunger until it locks, waiting for the fluid to stop flowing into the chamber (which occurs when the filter is covered with cells), placing the filter cell side down on a glass slide, applying fixative, blotting the filter, peeling the filter from the slide and fixing the slide in 95% alcohol. A monolayer of cells is deposited within an 18 mm diameter circle. Background material such as blood, inflammatory debris and mucus are eliminated. According to the manufacturer, the Cyto-Tek MonoPrep system is equivalent to automated systems and consistently produces slides with cells that exhibit optimal morphology with crisp nuclear detail, and preserves the architectural features of small cell aggregates.

P.1590

LIQUID-BASED AUTOMATED PREPARATIONS OF NONGYNECOLOGIC SAMPLES

The use of automatic monolayer devices for the preparation of nongynecologic material is becoming popular. These instruments were originally developed to prepare slides from gynecologic material for automated screening systems. AutoCyte Prep, now called SurePath (TriPath, Inc), and the ThinPrep Processor (Cytoc Corp) have both been approved for preparation of nongynecologic material. See above for a description of these devices. Many

workers endorse their use, rating the slides superior to slides made by less expensive conventional techniques. Other investigators refute the findings of improved quality and adequacy, contending that diagnostic accuracy may be adversely affected by cell shrinkage, dispersion or clustering caused by the automated preparation devices.

It is interesting to note, that while the debate continues over the efficacy of these instruments over conventional preparatory methods, another debate is in progress over the efficacy of purposely allowing slides to air dry and rehydrating them in saline as opposed to conventional wet fixation methods. The artifact produced by the air drying method is opposite to that of the liquid based systems which causes cells to shrink, in that cells are enlarged and exhibit better morphologic features. Proponents of both methods use such adjectives as "exquisite cytologic detail," "superior cytomorphology," "improved cytologic detail," and "preferred by cytotechnologists." These, and all methods of preparation, produce unique artifacts. Which method is used is usually a matter of personal preference and experience. We suggest that specimens be prepared by the same method within each laboratory so that a firm set of criteria can be established. We do not recommend one method over another; however, we do believe that when a procedure adds substantial costs, such as that associated with automated devices, continued unbiased investigation must be undertaken to justify their use over older and proven, much less expensive cytopreparatory procedures. For comments on processing of FNAs, see Chapter 28. It has been proposed that residual material collected by the ThinPrep method can be processed as **cell blocks** (Keyhani-Rofagha and Vesey-Shecket, 2002; Akpolat et al, 2004).

PREPARATION OF CELL BLOCKS

Cell block technique or paraffin embedding of sediments of fluids is among the oldest methods of preparing material for microscopic examination. The method uses histologic techniques for processing and thus offers one major advantage: multiple sections of the same material may be processed for routine stains, such as hematoxylin and eosin, and for special stains that may serve for immunocytochemistry and for identification of mucin, melanin, or other cell products, and identification of bacteria and fungi.

With the development of excellent cell preparation techniques, described in the foregoing pages, the cell block technique has been abandoned by many laboratories. This neglect is not justified in our opinion. The cell block technique should be used for processing all residual material remaining after completion of cytologic preparations. This material often contains valuable diagnostic evidence and tissue fragments that cannot be processed by cytologic techniques. Richardson et al (1955) have shown that additional diagnoses of cancer can be obtained in 5% of fluid specimens if smear technique is supplemented by cell block sections of residual material. The additional benefit of cell block technique is the recognition of histologic patterns of disease that sometimes cannot be reliably identified in smears or filter preparations.

Aspiration biopsy material (FNA), but also sputum, effusions, urine sediment, and material from the gastrointestinal tract, are suitable for cell block processing, as are all tissue fragments incidentally obtained during any other diagnostic cytologic procedure.

In our experience, **the best cellular details in cell blocks are obtained with Bouin's fixative or picric acid fixative**. However, a more **practical fixative is buffered formalin** that allows a wide range of additional procedures.

Methods

Fixed Sediment Method

1. Mix sediment or tissue fragments in one of the fixatives recommended for cell blocks. If the sediment is bloody, the blood may be hemolyzed prior to the addition of fixative by one of the methods described above. Fibrin clots can be wrung out as described previously and placed in fixative. Steps 2 and 3 are not necessary for fibrin clots.
2. Centrifuge this mixture for 10 minutes at the appropriate rpm (see above).
3. Pour off supernatant and drain tube well by inverting the tube on a paper towel.
4. Carefully remove the packed sediment or fibrin clot from the test tube by means of a spatula and wrap it in lens paper. Place wrapped sediment in a carefully labeled tissue cassette.
5. Put tissue cassette into a jar of the same type of fixative used in step 1. Process as tissue.

Bacterial Agar Method (3% Agar)

Steps 1 through 3 are the same as for the fixed sediment method.

4. If sediment becomes hard and packs well, gently remove it from the test tube with a spatula and place it, conical side up, on a paper towel.

5. Slice the sediment in half from the top to the bottom of the conical clot with a scalpel.
6. Place the cut side of the packed sediment in a small pool of melted agar that has been spread on a glass slide or in a Petri dish. Cover all exposed areas of the sediment with melted agar and let stand a few minutes to harden. *Care must be exercised to avoid bubbles in the agar.*
7. Trim the excess agar from the sediment and place the agar button in a tissue cassette.
8. Same as step 5 of the fixed sediment method.

P.1591

9. If sediment does not pack well or only a small amount is available after completion of steps 1 through 3, a few drops of melted agar should be added to the test tube and mixed thoroughly with sediment. After the agar hardens, gently remove the agar button from the test tube and cut it in half as described in step 5 before placing it into fixative.

Preparation of Agar

The 3% agar is prepared by dissolving 3 g of bacterial agar in 100 ml of boiling water. The melted agar may be colored with a small amount of food coloring to ensure contrast with the paraffin. The dissolved agar should be poured into individual sterile glass tubes with a screw cap. Cap the tubes loosely until the agar cools and hardens. When the agar has cooled, tighten the caps and place the tubes in a refrigerator until ready for use. When it is needed, melt the agar in a 60°C water bath. Discard unused agar at the end of the day.

Simplified Cell Block Technique

In 1988, Krogerus and Anderson introduced a simple technique for the preparation of cell blocks from material obtained by fine-needle aspiration, brushings, and effusions. The technique is unique in that the procedure is carried out in the sample tube, ensuring minimal cell loss. No transfer of cells to a cassette is necessary, eliminating the need for wrapping paper, agar, or thrombin. The procedure is as follows:

1. In a 50-ml plastic, conical centrifuge tube, fix cell sample with 50% alcohol for 1 hour.
2. Spin sample at 300 g for 7 minutes and pour off supernatant.
3. Re-suspend cell pellet in 3 ml of acetone for 10 minutes.
4. Spin sample at 300 g for 10 minutes. Pour off acetone.
5. Place tubes for 1 hour on a warm plate (not more than 60°C).
6. Add melted paraffin to the dry, warm pellet.
7. After paraffin has solidified, tap the bottom of the tube to remove block.
8. Cut and process the conical end of the paraffin block as you would any tissue section.

Plasma-Thrombin Clot Method

1. Thoroughly mix a few drops of outdated blood plasma obtained from blood bank with the fresh unfixed sediment. Plasma may be colored with a small amount of food coloring to ensure contrast with the paraffin. **If the sample was prefixed with alcohol, the sediment must be washed several times with a balanced salt solution**, since alcohol inhibits the clotting action of plasma and thrombin.
2. Add the same number of drops of thrombin solution as of the pooled plasma and mix well. (Thrombin, 5000 units, topical, 1 vial: Add 10 ml of distilled water.)
3. This mixture will form a clot in 1 to 2 minutes if the reagents are fresh and not too cold. Place resulting clot in a cassette that has been lined with lens paper to prevent the clot from oozing through the holes.
4. Same as step 5 of the Fixed Sediment Method. This clot is very soft and a spatula, instead of a forceps, is recommended for transfer to the embedding mold.

Compact Cell Block Technique

Yang et al (1998) described a technique that produces a compact cell block about 10% to 20% the size of conventional cell blocks. Cells are packed into a small area free of erythrocytes and extracellular protein, thereby reducing screening time, and often eliminating the need for deeper cuts.

1. Pour off the supernatant after centrifugation of 40 cc of a well mixed aliquot of the sample.
2. Mix the sediment with an equal volume of CytoRich Red.

3. After 2 minutes, add 4 drops of plasma and 3 drops of thrombin (5,000 μ l/10 ml).
4. Gently agitate the mixture. When the clotting stops, slide the clot onto lens paper that has been placed on top of paper towels.
5. Fold the lens paper over the clot and press and mold the clot flat and compact with a gloved fingertip. Wrap the compact clot tightly in lens paper and place in fixative of your choice.

Processing of Tissue Fragments from Smears

Papalioannou et al (1997) described a method for preparing cell blocks from **tissue fragments obtained from fine needle aspirations** using **cigarette rolling paper**. Smears are prepared as usual and wet fixed in 96% ethyl alcohol. The syringe and needle are rinsed with fixative and expelled into the fixative jar. Thick tissue fragments are scraped from the surface of the slide into the fixative. The fixative is filtered through a single sheet of commercially available cigarette rolling paper that has been placed in a funnel with filter paper used for support. The cigarette paper is folded, placed in a cassette, and submerged in a 9:1 mixture of 96% ethyl alcohol and 4% buffered formalin. After one-half hour, it is transferred to 96% ethyl alcohol. It is then processed as any tissue. Sections are suitable for special and immunocytochemical stains.

Verbeek et al (1996) described a method of removal of small tissue **fragments from stained cytology smears** for histology processing that leaves the cytology slide undamaged. The method can be used on gynecologic and nongynecologic material. Both immunocytochemistry and routine stains can be done on the paraffin processed histologic sections.

Prior to removing the coverslip, the location of the microbiopsy is marked with a diamond pen on the underside of the slide. After the coverslip is removed, a thick layer of mounting medium is poured onto the slide and allowed to dry for 45 minutes. The mounting medium surrounding the targeted microbiopsy is cut with a scalpel and gently removed from the surface of the slide. The microbiopsy is not destained but placed in xylene for 30 minutes and then embedded in paraffin from which 2 μ sections are cut and stained as usual. The slide from which the microbiopsy was

P.1592

removed is soaked in xylene to remove the excess mounting medium and then recoverslipped. An alternate method of analysis of thick tissue fragments is by the costly and timeconsuming method of confocal microscopy (see Chap. 2).

Microwave Technique for Rapid Processing of Cell Blocks

Since the early 1970s, microwaves have been used by histopathology laboratories to shorten fixation and processing times of tissue samples. In 1988, Kok et al described a method in which cell blocks from fresh sputum can be prepared in 35 minutes. The method can be adapted for use with other types of specimens.

Best results were obtained with a fixative consisting of 500 ml 96% ethyl alcohol, 430 ml of distilled water, and 70 ml of polyethylene glycol.

1. Place sputum in 40 ml of fixative in a microwave-safe jar.
2. Microwave sample at 450 watts with the temperature set at 70°C. This usually takes 5 minutes.
3. Place the sputum, which has become condensed and rubbery, into a tissue cassette. Put the cassette into 40 ml of absolute ethyl alcohol and microwave at 450 watts and 70°C. This usually takes 3 minutes; however, let the cassette sit in the microwave for another 2 minutes.
4. Transfer cassette to 40 ml of Histoclear (www.ralamb.net, Cat. #C-78G). Microwave at 450 watts or 80°C for 7 minutes.
5. Embed the material, cool blocks, cut and mount sections.
6. Sections can be de-paraffinized by placing them in Histoclear and microwaving them for 5 minutes at 700 watts and then stained by the method of choice.

Cell Blocks From Millipore Filters

Baloch et al (1999) described a technique for specimens of limited cellularity in which a portion of a Papanicolaoustained Millipore Filter (Millipore Corporation) can be converted into a cell block if other stains or immunocytochemical analysis are desired. In their hands, the technique produced H&E preparations with superb morphologic detail and excellent results for all antibodies tested. The background staining often seen in routine cell blocks was not seen in most cases. Since only half of the filter is used, the original cytologic preparation is preserved.

1. Remove filter after soaking slide in xylene to remove coverslip.

2. Rinse filter in a 1:1 solution of propanol and xylene for 5 minutes to remove all traces of mounting medium.
3. Roll the filter into a tube, cut in half and place into a cassette, fix in 10% neutral-buffered formalin. Embed and process as you would any tissue.
4. Remount the remaining half of the filter and return to cytology file.

Dehydration of Cell Blocks after Fixation.

Regardless of which method is used, the dehydrated paraffin-infiltrated cell block may be processed just as any other tissue. Histology laboratories usually process the cell blocks. However, if this service is not available, the following dehydration and embedding procedures may be used.

Dehydration after fixation by placing the cassettes in the following solutions:

1. 70% Alcohol (ethyl) 1 hour
2. 95% Alcohol (ethyl) 1 hour
3. 95% Alcohol (ethyl) 30 minutes
4. 95% Alcohol (ethyl) 30 minutes
5. Absolute alcohol 1 hour
6. Absolute alcohol 1 hour
7. Absolute alcohol 1 hour
8. Xylol 1 hour
9. Xylol 1 hour
10. Paraffin 2 hours
11. Paraffin at least 2 hours

Embed in clean paraffin, trim blocks, cut sections at 4 to 6 μ m, and mount on slides according to standard histologic techniques.

STAINING TECHNIQUES

Numerous staining techniques are available today for routine and for cytochemical and immunocytochemical purposes. Only those techniques that have practical value in diagnostic cytology, or that are mentioned in the text, are reported here. Numerous special books, listed in the appended bibliography, are available and may be consulted if additional staining techniques are desirable. See also Chapter 45.

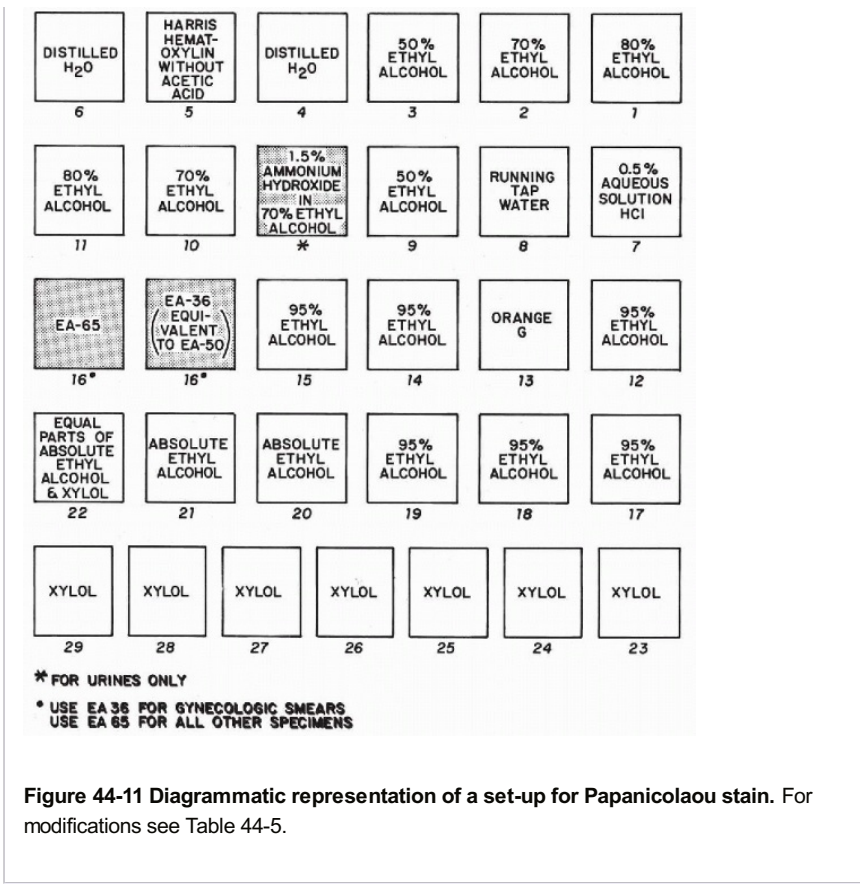

The Papanicolaou Stain

For routine diagnostic cytology, the Papanicolaou stain is recommended (two films are available from the American Society of Cytopathology, www.cytopathology.org/teach): "The Papanicolaou Stain: Principles" and "The Papanicolaou Stain: Materials & Methods"). The use of the Papanicolaou stain results in well-stained nuclear chromatin, differential cytoplasmic counterstaining, and cytoplasmic transparency. A modification of the original Papanicolaou stain (1942) was published by Dr. Papanicolaou in 1954. A set-up for the Papanicolaou stain is shown in Figure 44-11. Many modifications have been published by others. The intensity of nuclear stain and the depth and color of cytoplasmic staining are largely a matter of personal preference. Seven somewhat different modifications are described in Table 44-5. Staining times may be adjusted to produce results optimal for each laboratory.

Principal Characteristics of the Various Modifications of the Papanicolaou Stain

Hematoxylin

Papanicolaou **Technique I** uses Harris hematoxylin regressively. The cells are intentionally overstained and excess hematoxylin is removed by differential extraction in HCl.

Papanicolaou **Technique II**, originally described for urinary and gastric preparations, uses hematoxylin progressively. Differential extraction in HCl is not necessary, since the reduction in staining time prevents overstaining of the cytoplasm. Mayer hematoxylin and Gill hematoxylin rarely overstain nuclei, regardless of staining time, and are always used progressively. Progressive staining is usually recommended for cell samples that do not adhere well to glass slides, since the running water bath can be eliminated.

Eosin-Alcohol Stain

EA-36 and the commercial preparation, EA-50, have a similar formula. Each contains twice the amount of light green used in EA-65. This increased amount of light green in EA-50 and EA-36 tends to stain the background of thick nongynecologic smears too intensely, and for such smears EA-65 is preferred. EA-65 is also recommended by some authors for gynecologic smears, since the cytoplasmic staining reaction can help differentiate adenocarcinomas of the endocervix (pink) from those of the endometrium (blue). However, all of the EA formulas may be used for every type of sample stained.

Bluing

The substitution of bluing solutions for running water may be used for slides that frequently shed cells. The formulas for several such solutions are given below.

Hydration

The use of a series of graded alcohols (50%, 70%, 80%, and 95%) for hydration and dehydration was thought to minimize cell distortion. Gill replaced this series with one-step hydration and dehydration, which reportedly does not increase shrinkage.

P.1596

Materials Required

Staining Dishes

The type of staining dishes and slide carriers to be used depends on the number of cytologic specimens processed in any given laboratory. If the number of specimens is small, glass staining dishes (250 ml), with removable glass or metal carriers holding 10 slides, are adequate. Large numbers of slides are handled more quickly and easily if staining dishes of 1,000-ml capacity, accommodating a carrier for 60 slides, are utilized. Glass dishes are preferred for the stains and acid and alkaline solutions. Stainless steel dishes may be used for all other solutions. The stainless steel dishes are more expensive than glass dishes but more practical in the long run.

Stains

The Papanicolaou stains (EA-50, EA-65, and OG6) may be obtained commercially. Most of the companies making these stains also manufacture hematoxylin.

The commercially prepared stains are time-saving and usually very satisfactory. There are also complete Papanicolaou staining systems available such as that produced by Richard-Allan Scientific (www.rallansci.com) in which all of the reagents are designed to be used together. It is, therefore, prudent to start out by following the manufacturer's recommendations, and then making minor adjustments to suit individual preferences.

The stains may be prepared in the laboratory at a substantial saving. The formulas and methods of preparing stains and solutions used in the Papanicolaou staining method are given below.

Preparation of Stains and Solutions Used in the Papanicolaou Stain

The preparation of the essential solutions used in the Papanicolaou staining method is shown below. The formulas indicated may be used for the variants of Papanicolaou stain as shown in Table 44-5. A detailed discussion of general properties of dyes and chemicals may be found in the section on other stains.

Graded Alcohols

The formulas are listed in Table 44-6.

Solutions of Hydrochloric Acid

The formulas are listed in Table 44-7.

Bluing Solutions

There are several formulas for the bluing solutions of approximately equal value.

TABLE 44-6 PREPARATION OF GRADED ALCOHOLS (1,000 ML)

Desired Concentration (%)	Volume of Water (ml)	Volume of 95% Alcohol (ml)
50	474	526
70	263	737
80	160	840

1. *Ammonium hydroxide in 70% alcohol:* Add 15 ml of NH_4OH (28% to 30% weight/volume concentration) to 985 ml of 70% ethanol.
2. *Lithium carbonate: stock solution:* 1.5 g of LiCO_3 in 100 ml of water; *working solution:* Add 30 drops of stock solution to 1,000 ml of water.
3. *Scott's tap water substitute:* Dissolve in 1,000 ml of water 2 g of sodium bicarbonate and either 10 g magnesium sulfate, anhydrous (MgSO_4), or 20 g magnesium sulfate, crystalline (epsom salt).
4. *Tap water* can be used as a bluing agent if pH is higher than 8.

Alum Hematoxylin

The formulas for several variants are listed in Table 44-8. A list of hematoxylin certified by the Biological Stain Commission is shown in Table 44-9.

Harris Hematoxylin

1. Dissolve hematoxylin in alcohol.
2. Dissolve alum in water and bring to a boil.
3. Add dissolved hematoxylin to alum and water and bring again to a boil.
4. Remove flask from heat.
5. Immediately add mercuric oxide.
6. Stir this solution until a dark purple color appears.
7. Plunge flask into water bath to cool.
8. Filter and store in a dark bottle.

TABLE 44-7 PREPARATION OF SOLUTIONS OF HYDROCHLORIC ACID (1,000 ML)*

Desired Concentration (%)	1N HCl (ml)		Concentrated HCl (Approx. 12N) (ml)
0.5	60	or	5
0.25	30	or	2.5
0.05	6	or	0.5

* To a 1,000-ml graduated cylinder containing 700 ml water, add the volume of acid required for desired concentration. Let cool and add additional water to bring total volume to 1,000 ml.

TABLE 44-8 FORMULAS FOR ALUM HEMATOXYLIN (1 LITER)

Ingredients	Harris	Mayer	Lillie-Mayer	Gill (Half Oxidized)
Hematoxylin C.I. 75290	5 g	1 g	5 g	2 g [*]
Absolute methanol	50 ml	-	-	-
Water	1,000 ml	1,000 ml	700 ml	730 ml
Glycerol	-	-	300 ml	-

Chemical ripening agent	Mercuric oxide (HgO) 2.5 g	Sodium iodate (NaIO ₃) 0.2 g	Sodium iodate (NaIO ₃) 0.2-0.4 g	Sodium iodate [†] (NaIO ₃) 0.2 g
Aluminum ammonium sulfate (alum)	100 g	50 g	50 g	23.5 g or 17.6 g Aluminum sulfate
Glacial acetic acid	None [‡] or 40 ml [§]	None, 40 ml or 1 g citric acid	20 ml	20 ml or 1 g citric acid
Preservative	-	50 g Chloral hydrate	-	-
Stated Life	Months to years	2-3 months	Months to years	Over 1 year

^{*} 2.0 g anhydrous hematoxylin should be used. If the crystalline form is used, 2.36 g is required. Catalogs do not always describe whether anhydrous or the crystalline form is available. The anhydrous form is a fine powder that tends to cake. The crystalline form consists of small crystals that shift readily when the bottle is rotated while tilted.

[†] The sodium iodate should be weighed accurately to ± 0.01 g.

[‡] This formula is diluted with an equal volume of water for the Papanicolaou stain - Technique I.

[§] This formula is full strength for Papanicolaou stain - Technique II.

^{||} Saccomanno's technique substitutes 20 ml of normal acetic acid (16 ml of glacial acetic per 100 ml of water).

Mayer, Mayer-Lillie, and Gill (Half Oxidized) Hematoxylin

Combine the ingredients in the order listed in Table 44-8 and stir on a magnetic mix for approximately 1 hour at room temperature.

Cytoplasmic Counterstains (Orange G [OG] and Eosin-alcohol [EA])

The formulas for OG stains are listed in Table 44-10 and for EA stains in Table 44-11. The dyes are listed according to Color Index Number (Cl. No.). *The ingredients should be mixed as listed vertically and stored in well-stoppered dark bottles. Filter before using.*

Preparation of Solutions by Weight per Volume

Weight per volume solutions are used in making the stock aqueous and alcohol solutions for the counterstains used in the Papanicolaou staining techniques. For example, a 10% aqueous solution of OG would consist of 10 g of OG dye dissolved in 100 ml of water.

Modified EA and OG are based on **TDC**. The original formulas for EA and OG did not take into consideration the variability of the percentage of dye content from one batch of dye to another. For this reason, the use of TDC is being used to standardize the concentration of dyes in the EA and OG staining solution. The percentage dye concentration is printed on the label of certified dyes. To determine the weight of dye needed, divide number of grams of dye required by the percentage dye concentration. For example, if a 10% aqueous solution of OG was required and the dye content of the OG was 80%, $10 \text{ g} / .80 = 12.5 \text{ g}$ of that particular dye batch is needed. Alternately, if a 10% aqueous solution of Bismarck brown Y was needed and the dye content of the batch was 52%, $10 \text{ g} / .52 = 19.23 \text{ g}$ in 100 ml of water is needed to equal a TDC

of 10%.

Important Factors Influencing Staining Results

Maintenance of Solutions and Stains

Solutions may be used over a longer period of time if the slide carrier is rested on several thicknesses of paper toweling for a few seconds between staining steps. The life expectancy of stains may be increased by storing them in dark bottles when not in use and in keeping staining dishes covered.

The frequency of replacement of solutions required to ensure crisp, well-stained slides depends on the volume of slides processed daily. Daily microscopic checks are recommended.

The following schedule may be adjusted depending on the volume and nature of material processed.

- **Hematoxylin** remains relatively constant in staining characteristics and seldom requires discarding if small amounts of fresh stain are added daily to replace stain loss due to evaporation. However, the use of coating or Carbowax fixatives may result in contamination, making frequent changes necessary.
- **OG-EA** loses strength more rapidly than hematoxylin and should be replaced each week or as soon as the cells appear gray, dull, or without crisp contrasting colors.
- **Bluing solutions and HCl** should be replaced at least once daily.
- **Water rinses** should be changed after each use.
- **Alcohols** used during the rehydrating and dehydrating process, prior to the cytoplasmic stains, should be checked occasionally with a hydrometer and should be replaced weekly or may be discarded each day to avoid the necessity of filtering these solutions. The alcohol rinses following the cytoplasmic stains are usually changed on a rotating basis after each use. The alcohol rinse immediately following the stain is discarded and the other two rinses are moved into the first and second position, and the fresh, unused dish of alcohol is placed in the third position. This rotation continues after each staining run. The absolute alcohols should be changed weekly and can be kept water-free with the addition of Silica Gel pellets Type II (www.sigmaaldrich.com; catalog no. S7500).

P.1599

- **Xylene** should be changed as soon as it appears tinted with any of the cytoplasmic stains. Water in the xylene will make the solution appear slightly milky. The clearing process may be disturbed, and tiny drops of water can be seen microscopically on a plane above the cell on a slide. The addition of Silica-Gel pellets to the absolute alcohols will minimize the possibility of water contamination of xylene. They can also be added to the xylene to absorb any water that may be present.

Dipping Slides

Agitation of the slides by dipping is necessary to remove excess dye. If slides are not rinsed properly, a dull rather than sharp, crisp picture results. Slides should be dipped gently to avoid cell loss and the slide carrier should not hit the bottom of the staining dish. Each dip should last approximately one second. Dipping too slowly will result in too much decolorization. However, one or two dips more or less will not affect results.

Intensity of Staining Reaction

The desired intensity of nuclear and cytoplasmic stains is one of personal preference and varies with different cell samples. Individual experimentation is necessary. The quality of the stained slides is also dependent on the solubility, percentage of dye concentration, etc., of the dyes used in making EA, OG, hematoxylin, as discussed in the section of this chapter devoted to stain preparation.

Factors other than timing, however, may influence the nuclear and cytoplasmic staining intensity.

Trouble-Shooting With Papanicolaou Stain

Nuclear Stain Too Pale

Understaining of the nucleus may occur for one or more of the following reasons:

1. Contamination of hematoxylin with Carbowax or coating fixatives, which reduce its ability to penetrate the nucleus.

2. Time in hematoxylin is not increased for Carbowaxfixed specimens wherein the nuclei tend to resist hematoxylin penetration.
3. Decolorizing action of HCl continues if it is not removed carefully with running tap water.
4. Smears may have been permitted to air-dry prior to fixation.
5. Excessive time in chlorinated tap water will bleach the nuclear stain.
6. Carnoy's fixative results in loss of nuclear material if the smears are left in it for too long a time (see below).
7. The pH of the tap water or bluing agent is not sufficiently alkaline to blue properly.
8. Single cells may appear understained if thick areas of the smears are correctly stained.
9. Stain may become diluted if water is not drained from racks prior to immersion in hematoxylin.
10. If the timing of staining in hematoxylin is based on material collected in fixatives, unfixed material may have to be stained longer to achieve the same intensity of staining.
11. Concentration of HCl is greater than recommended or there were too many dips in HCl.
12. Expiration date of commercially prepared stain may have been overlooked.
13. Hematoxylin may be too old and should be replaced.
14. Inadequate mixing of the contents of aerosol and spray can fixatives result in poorly distributed fixation. Staining may be uneven and muddy in appearance. Shake all fixatives well prior to use.
15. Slides sprayed with aerosol fixatives at too close or too far a range result in pale, poorly stained slides (see above and Appendix to Chap. 8).
16. Waxes and oils from fixatives alter staining reactions if not adequately removed. Some brands may require the soaking of slides overnight in 95% alcohol, rather than merely rinsing them in alcohol prior to staining.

Nuclear Stain Too Dark

Overstaining of the nucleus may occur for one or more of the following reasons:

1. Cells fixed for a few minutes in modified Carnoy's shrink, causing some chromatin condensation. Therefore, staining time in hematoxylin must be decreased.
2. If timing of hematoxylin is based on staining slides prepared from fresh material, the time must be reduced for pre-fixed material.
3. Too few dips in HCl or acid concentrations is lower than recommended.
4. If single cells are well stained, thick areas of the slide may appear overstained.
5. Nuclepore filters that are dissolved prior to staining sometimes require less staining time in hematoxylin (see below).
6. The smears may have been prepared directly from very bloody or high-protein fluids. The sediments from these fluids should be washed with a balanced salt solution prior to slide preparation.
7. Slides were fixed in higher concentration of alcohol than is normally used.

Cytoplasmic Stains Unsatisfactory

The cytoplasmic stain may be unsatisfactory for the following reasons:

1. If the cytoplasmic stain is too pale, the slides may have been dipped excessively or remained too long in the alcohol rinses, which removes cytoplasmic color.
2. If there is no differential cytoplasmic staining (all cells appear pink), the slide may have been permitted to air-dry prior to fixation, or the slide may contain coccoid bacteria that alter staining reaction, or the stain may need replacement. If the slides were fixed with coating fixatives containing concentrations of alcohol greater than normally used, increased shrinking of the cells will

P.1600

occur. Increased timing is required in the EA for the dye to penetrate the dense cell wall.

3. Cytoplasm that appears somewhat gray or purple may result from excessive time in the hematoxylin or failure to remove excess hematoxylin from the cytoplasm with HCl.
4. When there is improper stain distribution, the margins of the cell clusters may stain blue or green, and the central thick portion of the smear may stain red or orange. This is the

consequence of insufficient staining time or the lack of agitation during staining and rinsing. The slides should be gently dipped to distribute dye throughout the thick portions of the smear and to remove excess dye trapped in the background.

5. If cytoplasm stains well but the colors appear too blue, green, or pink, the EA formula may have to be changed. EA50 and 36 contain twice as much light green as EA65. EA50, the commercial form of EA36, varies somewhat from manufacturer to manufacturer. Experimentation with different brands of EA50 and laboratory EA36 and 65 is necessary to obtain an acceptable cytoplasmic stain.
6. Inadequate mixing of the contents of aerosol and spray can fixatives can result in poorly distributed fixation. Staining may be uneven and muddy in appearance. Shake all fixatives well prior to use.
7. Slides sprayed with aerosol fixatives at too close or too far a range result in pale, poorly stained slides.
8. Waxes and oils from hairspray fixatives alter staining reactions if not adequately removed. Some brands may require the soaking of slides overnight in 95% alcohol rather than merely rinsing them in alcohol prior to staining.
9. Controlling the pH of the EA by the addition of 2 ml of glacial acetic acid per 100 ml of stain may give better and more consistent results.

Contamination Control

Hematoxylin, EA, OG-6 should be **filtered at least once daily**, particularly after staining slides containing cancer cells. A good-quality, medium-speed filter paper, such as Whatman No.1, removes most cells. In the *Cytotechnologist Bulletin* (vol. 12, 1975), Gill describes a stain filtration and storage system using a membrane filter to remove all cells. The alcohols used for rehydration and dehydration, the absolute alcohols, and xylenes must also be filtered or replaced daily. Regulatory agencies require that gynecologic and nongynecologic material be stained separately. Nongynecologic material may be stained together; however, to avoid cross-contamination from one slide to another in the same staining rack, it is recommended that those specimens notorious for shedding cells be stained in different staining dishes or at different times. Effusions containing numerous cancer cells are a common source of "floaters" that may attach to other slides. To screen out malignant effusions, rapidly mix a drop of sediment with toluidine blue or other suitable dye (see below). Such positive effusions should be stained separately and all stains and solutions filtered or discarded after use.

Regardless of the care used in staining, cross-contamination of slides may occur, and the occurrence of "malignant floaters" is particularly disturbing. If this happens, all solutions and stains should be immediately filtered or discarded. It is also wise to make a microscopic check of the mounting medium at this time to eliminate the possibility of being a source of contamination.

Important Factors Influencing the Staining Results of Filters

Millipore and Gelman filters should not be attached to a glass slide for staining. Clipping these filters to glass slides traps the stains and results in stain-streaked preparations. Clamp-style paper clips (Fig. 44-12) that allow filters to hang freely during the staining process may be used. Nuclepore filters may be clipped to a glass slide for staining.

Nuclepore filters differ in that prominent outlines of the filter pores remain after staining. Since the filter is birefringent, these pores cannot be made invisible by mounting in a medium of matching refractive index. A number of techniques have been developed to eliminate the pore outline including a process for dissolving the Nuclepore prior to staining (see below). This method, which has been modified, allows the slide to be placed in a staining rack and be stained in the usual manner.

Other methods include dissolving the filter after staining, transferring the cells from the filter to a glass slide (see above Methods of Transferring Cells From Filters to Glass Slides), or using a polarized light with a mounting medium with a refractive index that matches one of the two indices of the filter. Details of these procedures are discussed below.

1. During the staining sequences, Nuclepore filters behave similarly to glass slides with the exception of clearing in xylene. The time in xylene should be limited to 10

P.1601

to 15 minutes to prevent the filters from curling and rolling up tightly.

2. The background of Millipore and Gelman filters will stain with hematoxylin and the cytoplasmic stains. If the background is too heavily stained, cytologic detail and cellular

contrast are obscured. For this reason, Gill suggests the use of Mayer's or Gill's hematoxylin over Harris', which may stain the filter too intensely. After the water rinse following hematoxylin, the filter is slowly dipped approximately 30 times in a 0.025% or 0.05% solution of hydrochloric acid (HCl). The filter should appear pale yellow at this point. Apparently, the very low concentration of HCl does not decolorize the cells but is sufficient to partially decolorize the background of the filter.

3. As with hematoxylin, the background of the Millipore and Gelman filters is stained by EA and OG. To minimize stain retention, the filters should be rinsed for a longer period. Following OG, the slides must remain in three sequential 95% alcohol rinses, 1 minute each, with minimal dipping. The filters are stained for a long period in EA and are rinsed for 4 minutes, 2 minutes, and 1 minute, respectively, in three sequential 95% alcohol rinses. It is important that no dipping should occur during this sequence. Dipping will cause the stain to be removed from the cells as well as the filter background.
4. Absolute isopropyl alcohol must be substituted for the three final absolute ethanol rinses when staining Millipore filters. Absolute ethyl alcohol can soften and dissolve these filters.

Figure 44-12 Clamp for use with Millipore and Gelman filters.

Dissolving Nuclepore Filters Prior to Staining

1. Place Nuclepore filter (Fig. 44-13), cell side down, on a clean glass slide. Do not allow filter to dry.
2. Quickly blot the Nuclepore with Whatman No. 1 filter paper, folded in half, to make a double thickness. Roll a glass rod, print roller, or use finger pressure, once over and back, along the length of the filter.
3. Alcohol should remain under the filter. Quickly flood the filter with chloroform from a Pasteur pipette.
4. Place slide, still covered with chloroform, in a Coplin jar filled with chloroform for 20 to 30 minutes. Transfer slide to 95% alcohol. If a cloudy film appears, return slide to chloroform for 15 to 20 more minutes and then return again to alcohol. The slide may be placed in a rack for routine staining. Never permit the slide to air-dry.

Dissolving Nuclepore Filter After Staining *

1. Remove filter from xylene (see Fig. 44-13).
2. Place filter cell side down on dry glass slide or coverslip.
3. Blot filter with absorbent towel or filter paper. Roll a glass rod across, or press finger across, the surface to flatten filter at the same time.
4. Tilt slide or coverslip over a 4 × 4 gauze pad in a glass Petri dish. Start at center, working

toward each end, and gently flood the filter with chloroform from a Pasteur pipette.

5. Immediately place the slide or coverslip on the gauze and flood again with chloroform.
6. Place cover on Petri dish and allow chloroform to evaporate. High relative humidity and rapid evaporation will cause the filter to become cloudy.
7. After evaporation is complete, dip slide or coverslip in xylene and mount with Histoclad.

Ultrafast Papanicolaou Stain

Yang and Alvarez (1995) and Young (1995) developed a 90-second Papanicolaou stain for rapid assessment of fine needle aspirations (FNA). They report that the stain yields a transparent preparation with polychromatic stain and crisp nuclear details in a clear background. Several subsequent reports suggested that this stain offers excellent cytologic detail, particularly with malignant lymphomas and thyroid tumors.

Procedure:

1. Air dry FNA smears.
2. Rehydrate in normal saline 30 seconds
3. Alcoholic formalin (see below for formula) 10 seconds
4. Water 6 slow dips
5. Richard-Allan Hematoxylin 2 2 very slow dips
6. Water 6 slow dips
7. 95% ethanol 6 slow dips
8. Richard-Allan Cytostain 4 very slow dips
9. 95% ethanol 6 slow dips
10. 100% ethanol 6 slow dips
11. Xylene 10 slow dips
12. Mount and coverslip

Alcoholic Formalin: 65% Ethanol and 4% Formaldehyde

To prepare, combine 300 ml of 37% to 40% formaldehyde, 2,053 ml 95% ethanol and 647 ml of distilled water.

Destaining Slides

It is occasionally desirable to restain poorly stained slides, slides that have faded because of age, or when special stains are needed. It has been this author's experience that it is not necessary to destain Papanicolaou-stained slides prior to routine special stains, such as PAS, mucin and GMS. Simply removing the coverslip and mounting medium and rehydrating the slide as described below in steps 1-3 and then applying the new stain produces satisfactory results.

Some **immunological staining can also be done on previously Papanicolaou-stained smears** without the necessity of destaining. Abendroth and Dabbs (1995) used antibodies to keratin (CAM 5.2, AE1/AE3, and K903), epithelial membrane antigen, monoclonal carcinoembryonic antigen, desmin, muscle-specific actin (HHF-35), vimentin, leukocyte common antigen, B and T cell markers L26 and

P.1602

UCL-1, and prostate-specific antigen to stain unstained, alcohol-fixed or air-dried smear and compared them to previously Papanicolaou-stained smears that were either not decolorized or decolorized. All methods produced comparable results. However, Chen et al (1996) found that the Papanicolaou stain inhibited the polymerase chain reaction (PCR) when using primers to human β -globin and that decolorizing the smear removed the inhibitors. It is, therefore, recommended that parallel studies be performed using the antibodies unique to one's laboratory before deciding whether it is necessary to destain slides before application of new staining procedures. When destaining is necessary, the following procedure is useful:

Figure 44-13 Dissolving Nuclepore filters prior to (top) and after staining (bottom).

1. To remove the coverslip:
 - A. Soak in xylene until coverslip falls off, or
 - B. Heat slides on a warming plate at 60°C for 3 to 4 hours.
 - C. Place slides in freezer with coverslip down for a few minutes to half an hour (the older the slide, the less time is required). The coverslip should separate from the slide around the edges and should appear frosty. A razor blade should be slipped around the edges where the separation occurs, and the coverslip will come off easily.
2. Soak slide in xylene to remove old mounting medium.
3. Rinse slides well in two to three rinses each of absolute ethanol, 95% ethanol, and water. One minute in each of the alcohols and water is usually sufficient to remove all counterstains.
4. Place slides in aqueous 0.2% to 0.5% solution of HCl

P.1603

or 1% HCl in 70% alcohol for 5 minutes to 1 hour to remove hematoxylin. Slides should be checked under the microscope to see when decolorization has occurred.
5. Remove acid by rinsing in running tap water for 10 to 15 minutes. To ensure complete removal of the acid, slides should be placed in Scott's tap water substitute with a pH of approximately 8.2 and rinsed again in tap water.
6. Slides are now ready for restaining. If only the removal of cytoplasmic stains is desired, steps 1 through 3 may be used. Slides are then ready for restaining in OG and EA.

Mounting the Cell Sample

Mounting Media

A mounting medium creates a permanent bond between the slide and the coverslip. This permanent bond protects the cell film from mechanical damage, air-drying effect, and stain fading. To properly visualize cellular morphology, the refractive index of the glass, cellular material, coverslip, and mounting medium should closely match one another. Table 44-12 lists the refractive indices of various material used in cytology.

Regardless of the mounting medium used, it is important to maintain its pH as close to neutral as possible to prevent the fading of stains. One gram of 2, 6-di-tert-butyl-p-cresol (Butylated Hydroxytoluene) (www.sciencelab.com, Cat. #SLB 3511) can be added to 100 ml of any

mounting medium to **inhibit the fading of stains**. The mounting medium will thicken as the solvent evaporates. To maintain consistency, each new bottle of mounting medium should be checked by counting the number of drops that fall from a pipette filled with the fresh medium for 5 seconds. The number of drops should be noted on the label for future reference. Each week, the medium should be checked in a similar manner to determine if the addition of a solvent is necessary.

As shown in Table 44-12, Eukitt and Pro-Texx are best suited for Gelman and Millipore filters. Permount and Kleermount can also be used with good results. Histoclad is suitable for Nuclepore filters. However, because of the two refractive indices of this filter, the mounting medium cannot make the pores invisible. Some microscopists find these pores distracting and prefer to dissolve the filter to eliminate the pores. The filters may be dissolved prior to or after staining, as described below. Permount or Harleco HSR may be used with plain or frosted glass slides.

TABLE 44-12 REFRACTIVE INDICES OF VARIOUS MATERIALS USED IN CYTOLOGY

Slides, Filters, Coverslips	Index Refractive	Mounting Media	Refractive Index
Glass slide	1.515	Eukitt	1.4948
Glass slides, frosted	1.515	Harleco, HSR	1.5202
Coverslip #1 thinness	1.523	Histoclad	1.586
Coverslip #1 thinness	1.523	Permaslip	1.5
Gelman filter	1.47	Permount	1.5144
Millipore filter	1.495	Pro-Texx	1.495
Nuclepore filter	1.584 and 1.616	Coverbond	1.54

Eliminating Pores in Nuclepore Filters

Nuclepore filters have two refractive indices (1.584 and 1.616). It is, therefore, not possible to eliminate the outline of the pores by using a mounting medium with a similar refractive index. Ocklind (1987) developed a method whereby the pores can be visually eliminated by using a specially prepared mounting medium with a refractive index of 1.584 in combination with polarized light. Details of the method and mounting medium preparation are available in the cited reference.

Coverslipping

Selection of Coverslips

No. 1 glass coverslips in size 24 × 50 to 60 mm are recommended. The objectives of most microscopes are corrected for use with 0.170- and 0.180-mm coverslips, implying that a No. 1.5 coverslip would do well. However, this correction is based on tissue sections that are thinner than cytologic preparations. The thinner No. 1 coverslip will usually compensate better for this difference in thickness between tissue sections and smears.

Coverslip Application

Practice is necessary to achieve well-mounted slides, free of air bubbles and artifacts. A minimum of mounting medium should be used. Too much mounting medium interferes with microscopic detail, making the cell film appear hazy or milky when examined with the high dry objective. If the mounting medium and coverslip are applied too slowly, a common artifact appears as a brown, refractile pigment-like

P.1604

substance on the surface of the cells (Fig. 44-14). This artifact, sometimes referred to as “**cornflakes**” is caused by air trapped on the surface of the cell when xylene is allowed to evaporate. If this artifact occurs, the slide may be soaked in xylene, absolute alcohol, and 95%

alcohol, rinsed in running tap water, and restained in OG and EA. In stubborn cases, after the running water rinse, the slide may be placed in glycerine for one-half hour and rinsed well in tap water prior to reapplication of the counterstains.

Figure 44-14 Common coverslipping artifact—the appearance of a brown pigment-like substance on the surface of squamous cells, also known as “cornflakes.” (×560.)

Method of Coverslipping Glass Slides

1. Remove slide from xylene (Fig. 44-15).
2. Place one or two drops of mounting medium on the glass slide or coverslip.
3. Lower the coverslip over the glass slide to which mounting medium has been applied. Bubbles should be avoided at this point. Alternately, if the mounting medium is applied to the coverslip, lower the glass slide over the coverslip and then turn slide right side up. To prevent the possibility of contaminating the dropper and mounting medium with cells, the dropper should never touch the surface of the slide.
4. Gently tease bubbles from under the coverslip with an applicator stick and wipe excess xylene and mounting medium.

Figure 44-15 Method of coverslipping.

Coverslipping Millipore and Gelman Filters

Prior to mounting, 47-mm filters should be cut in half and the excess margin trimmed from all filters. This may be performed with scissors or a scalpel. The filters should be kept wet with xylene during cutting.

1. Dip a clean glass slide in xylene and drain off excess.

2. Place three to four drops of mounting medium on the glass slide and spread over the surface of the slide with the dropper or applicator sticks.
3. Remove filter from xylene and place filter *cell side up* on paper toweling to drain excess xylene. *Do not allow filter to dry.*
4. Place the filter *cell side up* on the glass slide, flatten the filter, and remove air bubbles by rolling an applicator stick or glass rod from the center out to each side of the filter.
5. Place four drops of mounting medium on the filter and gently lower a coverslip over the surface of the slide. *Do not drain excessive mounting medium.*
6. After carefully wiping the excess mounting medium from the bottom of the slide, allow slide to dry on a flat surface.

An alternate method of mounting Millipore and Gelman filters is as follows:

1. Remove filter from xylene.
2. Soak filter in undiluted mounting medium for 5 minutes.

P.1605

A separate dish should be used for each filter to avoid contamination. Plowden and Gill (1975) suggested the use of disposable 70 × 17 mm aluminum foil weighing dishes and recycling of the mounting medium by filtering it through a 7-μm pore size Millipore Duralon filter (Millipore Corporation; catalog no. NSG04700).

3. Remove the filter from the mounting medium and suspend the filter to allow the excess mounting medium to drain from the filter surface. The drops should stop falling. Excess mounting medium will make focusing difficult and the cells will appear milky or cloudy.
4. Lay the filter on a clean glass slide, *cell side up*, and gently lower the coverslip. Expel air bubbles that have been trapped by gentle pressure of an applicator stick.
5. Allow slide to dry on a flat surface.

Each of these two methods minimizes the risk of xylene evaporation and the drying of the filter, which can produce fern-like opacities.

Filters should be allowed to dry thoroughly on a flat surface before being permanently filed.

Cooking Slides for Rapid Screening

Graham's method of "cooking" slides allows them to be immediately screened. This procedure is not suitable for filters.

1. Remove slide from xylene.
2. Place three to four drops of mounting medium on glass slide and invert coverslip on top of glass slide.
3. Place slide on an electric hot plate set at medium temperature and covered with aluminum foil.
4. Leave the slide on the hot plate until the mounting medium bubbles evenly over the entire slide.
5. Remove the slide from the hot plate with forceps and press the surface of the coverslip to expel bubbles and excess mounting medium. Allow the slide to cool for a few minutes.
6. Clean the slide of excess mounting medium by rinsing in xylene or by removal with a razor blade.

Other Stains Useful in Diagnostic Cytology

The use of stains other than the Papanicolaou stain in routine diagnostic cytology has been limited. However, the ease with which cells can be obtained with the aid of a fine needle from organs that are not accessible to exfoliative cytology and advances in the understanding of the histochemical properties of cells has resulted in the greater application of immunocytochemical stains to cytologic material. Immunocytologic procedures and stains are discussed in Chapter 45. The stains listed in this text are not as routinely performed as they once were but still may be helpful at times. The principal staining procedures and their purposes are listed in Table 44-13.

All the staining procedures listed in this text may be used for cell blocks or smears unless otherwise indicated. Since there is a marked variation in the thickness of the paraffin sections and smears, it will be necessary to vary the times of staining in the different dyes to obtain good results. Individual experimentation is required.

Dyes

Dye powders should be obtained from reputable manufacturers and certified by the Biological Stain Commission. Certification ensures that minimum dye content levels are met and that the dye has been tested in staining procedures to see that it produces the classically described results. Dyes should be stored in a cool, dark place.

All dyes used in the procedures listed in this text can be obtained from Bio-Medical Specialists, Santa Monica, CA and E. Gurr Ltd, SW 14 London, UK.

Color Index Numbers (Cl. No.)

Names of dyes vary from region to region and country to country. For this reason, dyes have been cataloged by a five-digit number that unequivocally identifies the dye. The color index number should be specified when purchasing all dyes. For each dye listed in this text, the Cl. no. (Lillie and Fullmer, 1976) is provided, if available.

Dye Solubility and Impurities

The solvent for most dyes is either alcohol or water, or both. The methods described for preparation of the stains should be carefully adhered to in order to ensure maximum solubility. Most of the dyes currently available are purer than those produced in the past. However, all dyes with a dye content of less than 100% contain impurities that may help or hinder the staining reaction. It is, therefore, necessary to compare the results obtained from the dyes of different manufacturers and between two batches from the same manufacturer.

Total Dye Content

Dyes certified by the Biological Stain Commission must meet *minimum* dye content levels. However, there is still a marked variation in percentage dye concentration from one batch of dye to another. For example, the minimum percentage dye concentration of Bismarck Brown Y for certification is 45% and the percentage concentration of a recent batch submitted for certification was 52%. Unfortunately, very few published methods include the percentage dye content. Greater precision and accuracy will result if the amount of actual dye used is calculated. The percentage dye content of certified dyes is printed on the label. For example, if good results were obtained with 5 g of 93% basic fuchsin, the weight of the actual dye used was 4.65 g ($5 \text{ g} \times 0.93$). The amount of basic fuchsin required to yield similar results can then be calculated for different batches of dye. For example, the number of grams of dye needed to yield 4.65 g of actual dye from an 88% dye concentration of basic fuchsin would be:

Number of grams of new batch required = Total actual dye required/Concentration (new batch) or $\text{gx} = 4.65 \text{ g}/.88 = 5.28 \text{ g}$. In other words, 5.28 g of that particular batch of basic fuchsin is needed to obtain 4.65 g of actual dye.

P.1606

TABLE 44-13 STAINS WITH SPECIAL PURPOSE

Category	Use	Stain	Fixative
Histologic Sections or Aspiration Smears	Routine stain for paraffin sections and cell blocks	1. Hematoxylin and eosin	*A. 95% ethyl alcohol or equivalent
		2. Hematoxylin - orange eosin	
			†B. All fixatives listed previously
Hormonal Evaluation (Smears Only)	A single stain to differentiate superficial and intermediate cells	Shorr	A. 95% ethyl alcohol or equivalent
	Rapid wet method to differentiate superficial and intermediate cells	Rakoff	None

<i>Barr's Body</i>	Sharply differentiate sex chromatin from nuclear chromatin	1. Blebrich-Scarlet (Guard stain)	A. 95% ethyl alcohol or equivalent
		2. Acetic-Orcein	
		3. Cresyl-Violet (Moore and Barr)	
		4. Feulgen reaction	
<i>Pigments</i>	Bile	Fouchets method	A. 95% ethyl alcohol or equivalent
			B. All fixatives listed previously
	Melanin [‡]	Ferous ion uptake	Same as above
	Hemosiderin (Iron)	Prussian blue (Peris's)	A. 95% ethyl alcohol or equivalent
B. 10% buffered formalin			
<i>Microorganisms and Parasites</i>	<i>Sharply delineates fungi and Pneumocystis carinii</i>	Grocotts's methenamine silver (Churukian and Schenk)	A. 95% ethyl alcohol or equivalent
			B. 10% buffered formalin
	Stains fungi and cyst wall of <i>Pneumocystis carinii</i>	Gram-Weigert (Krajian)	A. 95% ethyl alcohol or equivalent, or air-dry
			B. 10% buffered formalin
	Stains most fungi	Periodic acid Schiff	A. 95% ethyl alcohol
			B. 10% buffered formalin
Capsule of cryptococcus	Mucicarmine (Mayer's)	A. Absolute ethanol or propanol	
		B. 10% buffered formalin	

	Stains most microorganisms and parasites	Giemsa Gram	A. 95% ethyl alcohol or equivalent or air-dried smears B. All fixatives listed previously
Carbohydrates	Stains all carbohydrates to identify colloid, fungi, glycogen, mucin, and so on	Periodic acid Schiff	A. 95% ethyl alcohol B. 10% buffered formalin
	Same as above except glycogen is eliminated	Periodic acid Schiff with diastase digestion	Same as above
	Specific for epithelial mucins	Mucicarmine (Mayer's)	A. Absolute ethanol or propanol B. 10% buffered formalin
Lipids	Stains all lipids	Sudan Black B	A. 37%-40% formalin vapors B. 10% buffered formalin
	Stains neutral fats to determine if histiocytes have phagocytized fat in lipid pneumonia	Oil Red O	Same as above
	Determination of fetal maturity	Nile blue sulfate	None
Nucleic Acids	Specific for DNA	Feulgen reaction	A. 95% ethyl alcohol or equivalent B. 10% buffered formalin
	Specifically differentiates RNA and DNA	Methyl green-pyronin (Kurnick's variant)	Same as above
Hematologic or Air-Dried Smears	Blood and bone marrow smears. Preferred by some for all cytologic	1. Wright stain 2. Giemsa stain 3. Wright-	A. Air-dried or 95% methyl alcohol

	material	Giemsa 4. May-Grünwald Giemsa	
Wet Cell Samples	Determination of fetal maturity	Nile blue sulfate	None
	Hormonal evaluation	Rakoff	None
	Differentiates histiocytes and leukocytes from neoplastic and mesothelial cells	Neutral red-Janus green (Foot and Holmquist)	None
	Rapid method for examining wet sediment	1. Thionine blue 2. Methylene blue 3. Toluidine blue	None
<p>* A = Fixative recommended for use with smears.</p> <p>† B = Fixative recommended for histologic sections.</p> <p>‡ Several immunostains such as HMB45 and Melan A103 are now available to document the presence of melanin.</p>			

P.1607

Preparation of Dyes and Solutions

Most staining solutions do not need to be prepared fresh whenever they are used. However, in some cases, two or more stock solutions are mixed immediately prior to use. Some of the methods presented in this text will list both stock and working solutions. When this is the case, it is always the working solution that is to be used in the staining procedure itself.

Table 44-13 lists the special stains contained in this text. Fixative *A* refers to the fixative recommended for smears and *B* refers to the fixative recommended for cell blocks. The use of improper fixatives will render staining results invalid in some procedures. Thus, close attention to the recommended fixative is suggested.

Routine Stain for Histologic Sections: Hematoxylin-Eosin

Preparation of Stains

Modified Harris' Hematoxylin

Hematoxylin Cl. No. 75290	5 g
Absolute alcohol (ethyl)	50 ml
Alum (ammonium or potassium)	100 g
Distilled water	1,000 ml
Mercuric oxide	2.5 g

1. Dissolve hematoxylin in alcohol.
2. Dissolve alum in water by aid of heat. Remove from heat and mix the two solutions.
3. Heat mixture to boiling point. Remove from heat and add mercuric oxide.
4. As soon as mixture turns a dark purple, cool quickly by plunging the vessel into cold water.
5. When cool, add 8 ml of glacial acetic acid to enhance nuclear stain.

Eosin

Eosin, Y Cl. No. 45380	16 g
Potassium dichromate	8 g
Picric acid (saturated aqueous)	160 ml
95% Alcohol (ethyl)	160 ml
Distilled water	1,280 ml

Dissolve eosin and potassium dichromate water; warm slightly if required. Add picric acid and alcohol.

Staining Procedure

Begin with step 1 for paraffin sections and step 8 for smears.

1. Xylol	5 minutes
2. Xylol	5 minutes
3. Absolute ethyl alcohol	15 dips
4. Absolute ethyl alcohol	25 dips
5. 95% Ethyl alcohol	15 dips
6. 80% Ethyl alcohol	15 dips
7. 70% Ethyl alcohol	15 dips
8. Wash in distilled water	15 dips
9. Harris's hematoxylin (modified—2 minutes or according to preference)	
10. Wash in running tap water until excess stain is removed (approximately 1 minute)	
11. Acid alcohol (1.5 ml of concentrated HCl in 650 ml of 70% ethyl alcohol)—two to three dips or until specimen is red in color	
12. Wash in running tap water	30 seconds
13. Lithium carbonate solution (1.5 ml saturated lithium carbonate solution, 650 ml of 70% ethyl alcohol)	1 minute
14. Wash in tap water	15 dips
15. 50% Ethyl alcohol	15 dips
16. Eosin	approximately 20 seconds
17. Wash in running tap water until excess stain is removed (approximately 1 minute)	
18. 95% Ethyl alcohol	15 dips
19. 95% Ethyl alcohol	15 dips
20. Absolute ethyl alcohol	15 dips
21. Absolute ethyl alcohol	1 minute
22. Xylol	15 dips
23. Xylol	15 dips
24. Xylol	5 to 10 minutes
25. Mount	

P.1608

Shorr's Stain (1941)

A single differential stain for hormonal evaluation of squamous cells in vaginal smears.

Components

Ethyl alcohol (50%)	100 ml
Biebrich scarlet Cl. No. 26905	0.5 g
Orange G Cl. No. 16230	0.25 g
Fast-green FCF Cl. No. 42053	0.075 g
Phosphotungstic acid	0.5 g
Phosphomolybdic acid	0.5 g
Glacial acetic acid	1.0 ml

Procedure

The solution should not be used until all the ingredients have dissolved completely.

1. Aspirate the vaginal secretion by means of a dry pipette with rubber bulb attached. Expel and smear on a glass slide. Alternately use scrape smears of lateral vaginal wall.
2. Fix, while wet, in 95% ethyl alcohol. Fixation for 1 or 2 minutes is adequate.
3. Stain for approximately 1 minute.
4. Carry through 70%, 95%, and absolute alcohol, dipping slide 10 times in each solution.
5. Clear in xylol and mount.

Results

The stain provides a sharp differentiation between cornified (fully keratinized) and noncornified squamous cells. The former stain a brilliant orange-red; the latter take on a green stain that is deeper in the younger cells and paler in the more mature ones. Other constituents, such as leukocytes, erythrocytes, bacteria, and spermatozoa, can be recognized.

Rakoff's Method

Rapid method of hormonal evaluation using wet smears.

Components

Light green Cl. No. 42095 5% Aqueous solution	83 ml
Eosin Cl. No. 45380 1% Aqueous solution	17 ml

Mix these two solutions.

Procedure

1. Moisten cotton-tipped applicator with saline solution or a scraper and make several vertical strokes along the lateral middle third of the vagina.
2. Drop swab into a test tube containing 1 to 2 ml of saline solution.
3. Place three drops of the Rakoff stain into the test tube and gently stir the solution with swab.
4. Transfer one to two drops of this mixture to a glass slide and coverslip.

Results

Cytoplasm stains brightly eosinophilic and basophilic. Vesicular nuclei are distinctly stained, while pyknotic nuclei have sharply stained margins but are pale.

Stains Used in the Identification of Sex Chromatin

Although vaginal smears may be used for the purpose of sex chromatin identification, buccal smears are preferable (see Chaps. 9 and 21). Obtain scrapings of buccal mucosa by drawing edge of metal spatula firmly over an area. Discard the first material and gently scrape the same area a second time to obtain deeper and better preserved cells. Smears taken from the soft palate also yield an abundance of well-preserved intermediate cells with vesicular nuclei. Make smear and immediately fix in 95% ethyl alcohol. It is always a good procedure to run a control

buccal smear along with the test smear.

One hundred single cells are counted. Count only those cells with unwrinkled, well-preserved, open vesicular nuclei. If only unequivocal sex chromatin bodies are counted, the count for males should be 0, and the count for females 20% to 40%.

Bierbrich Scarlet-Fast Green (H.R. Guard, 1959)

Components

Biebrich Scarlet Stain.

Biebrich scarlet-water soluble Cl. No. 26905 (Harleco)	1.0 g
Phosphotungstic acid	0.3 g
Glacial acetic acid	5.0 ml
50% Ethyl alcohol	100 ml

Fast-Green Stain.

Fast-green FCF (Harleco) Cl. No. 42053	0.5 g
Phosphomolybdic acid	0.3 g
Phosphotungstic acid	0.3 g
Glacial acetic acid	5.0 ml
50% Ethyl alcohol	100 ml

Staining Procedure

Our laboratory has found the following procedure to be satisfactory.

1. From fixative, transfer smear to 70% alcohol for 2 minutes.
2. Stain in Biebrich scarlet for 5 minutes.
3. Rinse in 50% alcohol.
4. Differentiate in fast-green FCF from 2 to 5 hours. During

P.1609

this step, check the differentiation under a microscope at hourly intervals. When all the cells reveal green cytoplasm and all the vesicular nuclei are also green, the reaction is complete, usually in approximately 4 hours. However, the pyknotic nuclei will not be differentiated and will be bright red.

5. Rinse in 50% alcohol and let remain in the alcohol for 5 minutes.
6. Dehydrate in 70%, 95%, and absolute alcohols for 2 minutes each.
7. Clear in 3 changes of xylol for 2 minutes each.
8. Mount with a permanent mounting medium.

Results

The nuclei stain pale green; the sex chromatin stains pink to red and is seen as a V-shaped or triangular condensation with the base attached to the nuclear membrane. A narrow halo is usually noted around the unattached side. A thin, single or multiple strand of chromatin material is often observed running from the sex chromatin body toward the center of the nucleus. For further details, see Chapters 4 and 29.

Acetic Orcein and Fast-Green Stain

Orcein (natural)	1 g
Hot glacial acetic acid	45 ml
Distilled water	55 ml

Heat acid to 80° to 85°C in flask placed in beaker containing water. Add orcein while shaking or stirring rapidly. Add distilled water while continuing to stir or shake flask. Stopper flask and place under cold running water. When the stain has cooled, filter and store in a brown bottle.

The stain keeps very well.

Fast green Cl. No. 42053 0.03 g

95% Ethyl alcohol 100 ml

Add fast green to the alcohol, and stir or shake to dissolve.

Staining Procedure

1. Fix smears in 95% ethyl alcohol for 30 to 60 minutes.
2. Hydrate slides through 80%, 70%, and 50% ethyl alcohol and distilled water—5 dips each.
3. Stain in acetic orcein stain for 5 minutes (a control slide should be used, as staining time in acetic orcein may vary according to the age of stain).
4. Wash for 10 seconds in distilled water.
5. Dehydrate in 50%, 70%, 80%, 95% ethyl alcohol—5 dips each.
6. Stain in fast green for 1 minute.
7. Wash in 95% ethyl alcohol, absolute ethyl alcohol, absolute ethyl alcohol, and equal parts of xylol—5 dips each. Clear in xylol for 5 minutes.
8. Coverslip preparation, using Permount.

Results

The sex chromatin body stains red, and the cytoplasm stains pale green. This stain also may be used for metaphase chromosomal preparations.

Cresyl Violet (Moore and Barr)

Components

Cresyl violet 1 g

Distilled water 100 ml

Staining Procedure

1. Water 5 minutes
2. Cresyl violet 7 minutes
3. 95% alcohol 3 minutes
4. 95% alcohol 2 minutes
5. Absolute alcohol 5 minutes
6. Xylene 15 dips
7. Mount with permanent mounting medium.

Results

The nuclei stain pale pink, and the sex chromatin stains deep pink to violet.

Stains for Pigments

Fouchet's Method for Bile

Components

Fouchet's Stock Solutions.

A. 25% Aqueous trichloroacetic acid

B. 10% Aqueous ferric chloride

Fouchet's Working Solutions.

Solution A 100 ml

Solution B 10 ml

Van Gieson's Picro-Fuchsin.

1% Aqueous acid fuchsin Cl. No. 42685 10 ml

Saturated aqueous picric acid 100 ml

Staining Procedure

Begin with step 1 for paraffin section and step 8 for smears.

1. Xylol 5 minutes
2. Xylol 5 minutes
3. Absolute ethyl alcohol 15 dips
4. Absolute ethyl alcohol 15 dips
5. 95% Ethyl alcohol 15 dips
6. 80% Ethyl alcohol 15 dips
7. 70% Ethyl alcohol 15 dips
8. Wash in distilled water 15 dips
9. Fouchet's working solution 5 minutes
10. Distilled water 1 minute
11. Distilled water 1 minute
12. Van Gieson's picro-fuchsin 5 minutes
13. 95% Alcohol 15 dips
14. 95% Alcohol 15 dips
15. Absolute alcohol 15 dips
16. Absolute alcohol 15 dips
17. Xylene 15 dips
18. Xylene 15 dips
19. Mount with permanent mounting medium.

Results

Bile pigments stain olive green, collagen stains red, and the background stains yellow.

P.1610

Ferrous Ion Uptake for Melanin**Stain Components**

1. Prepare a 2.5% aqueous solution of ferrous sulfate.
2. Prepare a 1.0% solution of potassium ferricyanide in 1% acetic acid.
3. Nuclear fast red Cl. No. 60760 (Kernechtrot): Heat to dissolve 0.1 g of nuclear fast red in a 5% solution of aluminum sulfate. Let cool, filter, and add a grain of thymol.

Staining Procedure

Begin with step 1 for paraffin sections and step 8 for smears.

1. Xylol 5 minutes
2. Xylol 5 minutes
3. Absolute ethyl alcohol 15 dips
4. Absolute ethyl alcohol 15 dips

5. 95% Ethyl alcohol 15 dips
6. 80% Ethyl alcohol 15 dips
7. 70% Ethyl alcohol 15 dips
8. Wash in distilled water 15 dips
9. Ferrous sulfate solution 1 hour
10. Distilled water 1 minute
11. Distilled water 1 minute each
12. Distilled water 1 minute each
13. Distilled water 1 minute each
14. Potassium ferricyanide 30 minutes
15. 1% Acetic acid 15 dips
16. Distilled water 15 dips
17. Nuclear fast red 1-2 minutes
18. Distilled water 15 dips
19. 95% Ethyl alcohol 15 dips
20. Absolute ethyl alcohol 15 dips
21. Xylol 15 dips
22. Xylol 15 dips
23. Mount in permanent mounting medium.

Results

Melanin stains dark blue to dark green, and the background stains red to pink. Several other more specific immunostains for melanin are now available, such as **HMB45** and **Melan A103** (see Chapter 45).

Prussian Blue Reaction for Hemosiderin (Iron) (Perls')

Components

- A. Potassium ferrocyanide 2% aqueous
- B. Hydrochloric acid 2%
- C. Neutral red Cl. No. 50040 1% aqueous

Staining Procedure

Begin with step 1 for paraffin-embedded tissue sections and with step 8 for smears.

1. Xylol 5 minutes
2. Xylol 5 minutes
3. Absolute ethyl alcohol 15 dips
4. Absolute ethyl alcohol 15 dips
5. 95% Ethyl alcohol 15 dips
6. 80% Ethyl alcohol 15 dips
7. 70% Ethyl alcohol 15 dips
8. Wash in distilled water 15 dips
9. Equal parts solution A and B 30 minutes

- | | |
|----------------------|------------------|
| 10. Distilled water | 15 dips |
| 11. Distilled water | 15 dips |
| 12. Distilled water | 15 dips |
| 13. Neutral red | 10 to 15 seconds |
| 14. Distilled water | 15 dips |
| 15. Distilled water | 15 dips |
| 16. Distilled water | 15 dips |
| 17. 95% Alcohol | 15 dips |
| 18. 95% Alcohol | 15 dips |
| 19. Absolute alcohol | 15 dips |
| 20. Absolute alcohol | 15 dips |
| 21. Xylene | 15 dips |
| 22. Xylene | 15 dips |
| 23. Mount | |

Results

Ferric iron-containing pigments (hemosiderin) stain blue; the nuclei stain red.

Stains for Microorganisms and Parasites

As a result of the AIDS epidemic, laboratories have been challenged by the dramatic increase of samples submitted for determination of the presence of organisms that cause opportunistic infections. Most notably, an increasing number of patients are presenting with respiratory infections. *Pneumocystis carinii* is high on the list of pathogens responsible for these infections. Gomori's and Grocott's methenamine silver stain have been the traditional methods of choice for demonstrating this organism. The silver stain has a greater individual sensitivity as compared to that of other methods since it gives good contrast between the background of the smear and the organism. An abundance of literature has sprung from modifications of the stain to make it easier and quicker to perform. A number of rapid methods have been reported that use hot plates, water baths, and microwave ovens to speed silver impregnation.

With experience gained from seeing numerous positive cases, many have reported success with other rapid stains such as Diff-Quick, cresyl violet, and the routine Papanicolaou smear. In the routine Papanicolaou stain, organisms appear in foamy, honeycombed masses that stain eosinophilic or basophilic and are often two-toned. Ghali et al (1980) reported that *Pneumocystis* emits bright fluorescence in routine Papanicolaou-stained smears, examined under ultraviolet illumination. (For further comments, see Chap. 19.)

Many of these alternatives have been used successfully in our laboratory. The sensitivity of each method in detecting *Pneumocystis carinii* ultimately depends on the experience of the observer rather than the specificity of the stain.

P.1611

Methenamine-Silver Stain: Grocott's Method

Demonstrates *Pneumocystis carinii* and fungi.

Components

1. Methenamine silver nitrate

Stock solution: Mix 100 ml of 3% methenamine (hexamethylenetetramine) and 5 ml of 5% silver nitrate. Shake well.

Working solution: Mix 25 ml of the stock solution with 25 ml of distilled water and 2 ml of 5% borax (sodium borate).

2. Fast Green FCF Cl. No. 42053

Stock solution: Dissolve 0.2 g of fast green in 100 ml of 0.2% acetic acid.

Working solution: Mix 10 ml of stock solution with 40 ml of distilled water.

3. Prepare 5% solution of chromium trioxide.
4. Prepare 1% solution of sodium bisulfite.
5. Prepare 0.2% solution of gold chloride.
6. Prepare 2% solution of sodium thiosulfate.

Staining Procedure

Start with step 1 for paraffin-embedded histologic sections and with step 8 for smears.

1. Xylol	5 minutes
2. Xylol	5 minutes
3. Absolute ethyl alcohol	15 dips
4. Absolute ethyl alcohol	15 dips
5. 95% Ethyl alcohol	15 dips
6. 80% Ethyl alcohol	15 dips
7. 70% Ethyl alcohol	15 dips
8. Wash in distilled water	15 dips
9. 5% Chromium trioxide (place Coplin jar with solution and slides in a 43°C water bath)	2 minutes
10. Transfer Coplin jar to a 58°C water bath	15 minutes
11. Tap water	15 dips
12. 1% Sodium bisulfite	30 seconds
13. Running tap water	15 seconds
14. Distilled water	15 dips
15. Distilled water	15 dips
16. Distilled water	15 dips
17. Distilled water	15 dips
18. Methenamine-silver (freshly mixed working solution). Place Coplin jar with solution and slides in 43° water bath	2 minutes
19. Transfer Coplin jar to a 58°C water bath	2-3 minutes
20. Distilled water	15 dips
21. Distilled water	15 dips
22. Distilled water	15 dips
23. Distilled water	15 dips
24. 0.2% Gold chloride (depends on freshness)	20 to 30 dips
25. Distilled water	15 dips
	15 dips

26. Distilled water	each
27. 2% Sodium thiosulfate	1 minute
28. Running tap water	15 seconds
29. Fast green (working solution)	30 seconds
30. Running tap water	15 seconds
31. Distilled water	15 dips
32. Distilled water	15 dips
33. 95% Ethyl alcohol	15 dips
34. 95% Ethyl alcohol	15 dips
35. 95% Ethyl alcohol	15 dips
36. Absolute ethyl alcohol	15 dips
37. Absolute ethyl alcohol	15 dips
38. Xylol	15 dips
39. Mount with permanent mounting medium.	

Results

Pneumocystis carinii and fungi stain black, sharply delineated; glycogen and mucin stain rose to gray; and the background stains pale green.

Gram-Weigert Stain

Demonstration of fungi and cyst wall of *Pneumocystis carinii*.

Components***Eosin.***

Eosin Y Cl. No. 45380	1 g
Distilled water	100 ml

Gentian Violet (Sterling's).

Crystal violet Cl. No. 42555	5 g
95% Ethyl alcohol	10 ml
Aniline oil	2 ml
Distilled water	88 ml

Dissolve the crystal violet in the 95% ethyl alcohol and add this to the mixture of aniline oil and water that has been previously filtered.

Iodine Solution (Gram's).

Iodine	1 g
Potassium iodide	2 g
Distilled water	300 ml

Dissolve the potassium iodide in water and then add the iodine.

Staining Procedure

Start with step 1 for paraffin sections and with step 8 for smears.

- | | |
|--|---|

P.1612

Results

Pneumocystis carinii (cyst wall), gram-positive bacteria and fungi stain violet, Gram-negative organisms are not stained, and fibrin stains blue-black.

Gram's Stain

Distinguishes Gram-negative from Gram-positive bacteria.

Components**Lillie's Crystal Violet.**

Crystal violet Cl. No. 42555	5 g
95% Alcohol	50 ml
Ammonium oxalate	2 g
Distilled water	200 ml

Dissolve the crystal violet in the alcohol and the ammonium oxalate in water. Combine the two mixtures and filter prior to using.

Lugol's Iodine.

Iodine	1 g
Potassium iodide	2 g
Distilled water	100 ml

In a mortar with a small volume of water, grind the iodine and potassium iodide. Pour off the supernatant, add another small volume of water, and grind again. Continue these steps until the crystals are completely dissolved. Add remaining water to this solution.

Neutral Red Cl. No. 50040. Prepare a 1% aqueous solution.

Staining Procedure

Start with step 1 for paraffin sections, with step 8 for fixed smears, or step 9 for air-dried smears.

1. Xylol 5 minutes
2. Xylol 5 minutes
3. Absolute ethyl alcohol 15 dips
4. Absolute ethyl alcohol 15 dips
5. 95% Ethyl alcohol 15 dips
6. 80% Ethyl alcohol 15 dips
7. 70% Ethyl alcohol 15 dips
8. Wash in distilled water 15 dips
9. Crystal violet 1 to 2 minutes
10. Tap water 10 dips
11. Lugol's iodine 30 seconds to 1 minute
12. Tap water 10 dips
13. Acetone 10 to 15 dips
14. Running tap water 5 to 10 minutes
15. Neutral red 30 seconds to 1 minute
16. Tap water 15 dips
17. Tap water 15 dips
18. Tap water 15 dips

20. 95% Alcohol 15 dips
21. Absolute alcohol 15 dips
22. Absolute alcohol 15 dips
23. Xylene 15 dips each
24. Mount in permanent mounting medium.

Results

Gram-positive organisms stain blue-black, gram-negative organisms stain red, and the background stains pink.

Stains for Carbohydrates

Periodic Acid-Schiff Reaction (PAS)

Components

Periodic Acid. Prepare a 1% aqueous solution.

Schiff Reagent.

- | | |
|-----------------------------------|--------|
| Distilled water | 100 ml |
| Basic fuchsin Cl. No. 42500 | 1 g |
| Sodium or potassium metabisulfite | 2 g |

1N HCl	20 ml
--------	-------

Activated charcoal	0.3 g
--------------------	-------

Bring water to a boil and remove from heat. When solution cools to 60°C, add the basic fuchsin. Filter and then add the sodium or potassium metabisulfite and HCl. Pour this solution in a stoppered, dark bottle and keep at room temperature for 18 to 24 hours. Add the charcoal and vigorously shake mixture for 1 minute. Filter this solution and store at 0° to 5°C. Discard this reagent when a pink color develops.

Sodium Metabisulfite Solution.

Stock solution: Prepare a 10% aqueous solution.

Working solution: 5 ml of stock mixed with 100 ml of distilled water.

Pal's Bleach.

Pal's Bleach.

Oxalic acid	0.5 g
-------------	-------

Potassium sulfite	0.5 g
-------------------	-------

Distilled water	100 ml
-----------------	--------

Fast Green.

Fast green FCF Cl. No. 42053	1 g
------------------------------	-----

1.0% Acetic acid	100 ml
------------------	--------

Weigert's Iron Hematoxylin.

Solution A.

Hematoxylin	1 g
-------------	-----

Alcohol 95%	100 ml
-------------	--------

Solution B.

Ferric chloride 29% aqueous	4 ml
-----------------------------	------

Distilled water	95 ml
-----------------	-------

HCl, concentrated	1 ml
-------------------	------

Working solution: equal parts of solutions A and B.

P.1613

Staining Procedure

Start with step 1 for paraffin sections and step 8 for smears.

1. Xylol 5 minutes
2. Xylol 5 minutes
3. Absolute ethyl alcohol 15 dips
4. Absolute ethyl alcohol 15 dips
5. 95% Ethyl alcohol 15 dips

Results

All carbohydrates and fungi stain magenta, nuclei stain black, and the background stains green.

Periodic Acid-Schiff (PAS) With Diastase Digestion**Components**

The same solutions as used for the PAS without diastase digestion with the addition of the following:

Diastase Solution.***Diastase Solution.***

Diastase of malt, USP	0.5 g
Distilled water	100 ml

Staining Procedure

The staining procedure is the same as that for PAS except that one of the slides is placed in the diastase solution for 20 minutes prior to step 9.

Results

All carbohydrates, including glycogen and fungi, will be PAS-positive (magenta red) in standard PAS-stained slide. Glycogen will be unstained in the diastase-treated slide.

Mayer's Mucicarmine**Components*****0.25% Metanil Yellow Solution.***

Metanil yellow Cl. No. 13065	0.25 g
------------------------------	--------

Distilled water	100 ml
Glacial acetic acid	0.25 ml

Mucicarmine Solution.**Stock solution:**

Carmine Cl. No. 75470	1.0 g
Aluminum chloride, anhydrous	0.5 g
Ethyl alcohol (50%)	100 ml
Aluminum hydroxide	1.0 g

Pour the alcohol in a 250-ml flask and add the carmine and aluminum hydroxide. In a mortar, grind the aluminum chloride and add it to the flask. Mix the solution well, rapidly bring it to a boil, and boil for 2.5 minutes. Shake the mixture frequently. Place the flask under running tap water to cool it rapidly. Filter and store. Shelf life is approximately 3 months.

Working solution:

Mucicarmine stock	25 ml
Tap water	75 ml

Pal's Bleach. (see above)

Weigert's Iron Hematoxylin. (see above)

Staining Procedure

Start with step 1 for paraffin sections and with step 8 for smears.

1. Xylol 5 minutes
2. Xylol 5 minutes
3. Absolute ethyl alcohol 15 dips
4. Absolute ethyl alcohol 15 dips
5. 95% Ethyl alcohol 15 dips
6. 80% Ethyl alcohol 15 dips
7. 70% Ethyl alcohol 15 dips
8. Wash in distilled water 15 dips
9. Weigert's hematoxylin 4 minutes
10. Running tap water 4 minutes
11. Pal's bleach 1 dip
12. Running tap water 10 minutes
13. Mucicarmine 60 minutes
14. Distilled water 5 dips
15. Metanil Yellow 1 minute
16. Distilled water 5 dips
17. 95% Alcohol 15 dips
18. 95% Alcohol 15 dips
19. Absolute alcohol 15 dips
20. Absolute alcohol 15 dips

21. Xylene 15 dips
22. Xylene 15 dips
23. Mount in permanent mounting medium

Results

Mucin stains deep rose to red, capsule of *Cryptococcus* stains deep rose to red, nuclei stain black, and other tissue elements stain yellow.

P.1614

Stains for Lipids***Sudan Black B for Smears*****Components****Stock solution:**

Sudan Black B Cl. No. 26150 0.3 g

Absolute ethyl alcohol 100 ml

Shake the mixture vigorously and frequently for 1 or 2 days until the dye is dissolved. Then filter.

Working solution:

Sudan Black B Stock 30 ml

Buffer 20 ml

Filter, using suction through double-thickness No.1 filter paper. This solution will keep for 2 to 3 weeks.

Buffer

Phenol crystals 16 g

Absolute ethyl alcohol 30 ml

Na₂HPO₄* 0.119 g in 100 ml of water

* Mayer's Hematoxylin: MHS-1 Eosin Y Cl. No. 45380: 0.01% Aqueous Acetic Acid: 0.5% Solution (Sigma-Aldrich Co.)

Staining Procedure

1. Fix smear in formalin vapors (see above) 10 minutes
2. Air-dry 10 minutes
3. Sudan Black B 30 minutes
4. 70% Ethyl alcohol (2 changes) 2 minutes each
5. Distilled water 15 dips
6. Mayer's hematoxylin 5 minutes
7. Distilled water 10 to 15 minutes
8. 0.01% Eosin Y 1 dip
9. 0.5% Acetic acid 1 dip
10. Distilled water 15 dips
11. Blot and air-dry

Results

Phospholipids and granules of granulocytic series stain black, RBC stain pink, and nuclei stain

blue.

Oil Red or Fat Stain

Occasionally, it may be necessary to stain smears for fat. This may be the case with sputum or bronchial washings if there is a suspicion of lipoid pneumonia. When fat stain is required, smears should be prepared from fresh, unfixed material and fixed in formalin vapors.

Preparation of Stains and Mounting Medium

Oil red, O Cl. No. 26125 1-2 g

Alcohol, 70% 50 ml

Acetone 50 ml

Harris' hematoxylin is used as a counterstain.

Glycerine jelly

Gelatin 10 g

Distilled water 60 ml

Heat until gelatin is dissolved.

Add:

Glycerin 70 ml

Phenol 1 ml

Staining Procedure

1. Dip in 70% alcohol for just a second.
2. Place in a tightly closed container of oil red 0 for 5 minutes or longer (up to 1 hour).
3. Wash very quickly in 70% alcohol.
4. Wash in water.
5. Counterstain in Harris's hematoxylin for a few minutes.
6. Wash in water.
7. Blue in ammonia water. If smears appear too dark when removed from hematoxylin, differentiate in 1% acetic acid in water solution for a few seconds and then blue in ammonia water.
8. Wash in water.
9. Mount in glycerin jelly.

Results

Fat stains orange to bright red, and nuclei stain blue.

Stains for Nucleic Acid

Feulgen Stain *

This is for specific staining of double-stranded deoxyribonucleic acid. Commercially available Feulgen stain, especially provided for a DNA measuring instrument, the CAS 200 is available from TriPath Imaging, Inc (Burlington, NC), as the Quantitative DNA Staining Kit. A DNA standard calibration-control slide may also be ordered from the same company.

Procedure

1. Bring paraffin sections through xylene and alcohol to water as usual, with the usual iodine thiosulfate sequence for removal of mercurial precipitates if required, or use alcohol-fixed smears.
2. Place in normal hydrochloric acid (preheated) at 60°C for 10 minutes.
3. Immerse in Schiff's reagent for 10 minutes (see above).
4. Wash 2 minutes in each of three successive baths of 0.05 M metabisulfite. The sulfite baths should be discarded daily.

5. Wash 5 minutes in running water.
6. Counterstain a few seconds in 0.01% fast-green FCF Cl. No. 42053 in 95% alcohol. The stain does not wash out in alcohol, but if it is too intense, it may be removed promptly in water.
7. Complete the dehydration with 100% alcohol; clear through one change of alcohol and xylene (50:50) and two of xylene. Mount in polystyrene, ester gum, Permount, HSR, or other synthetic resin or in balsam.

Results

Nuclear chromatin is a deep red-purple.

P.1615

Kurnick's Methyl Green-Pyronin Variant (after Lillie, 1965, p 154)

For demonstration of ribonucleic acid.

Procedure

1. Fix in any one of the following: Carnoy, cold 80% alcohol, cold acetone, neutral formalin; embed and section in paraffin as usual or use frozen dried material embedded in paraffin directly. Alcohol fixed smears may be used. Deparaffinize and hydrate as usual (*smears need only to be rinsed in distilled water prior to step 3*).
2. Stain 6 minutes in repurified 0.2% methyl green (*Methyl green Cl. No. 4258*) in water or in pH 4.2 M/100 acetate buffer. (The solution should be extracted in a separate funnel by shaking with successive changes of chloroform until no more color is extracted).
3. Blot dry and dehydrate with two changes n-butyl alcohol.
4. Stain 30 to 90 seconds in acetone freshly saturated with pyronin (*Pyronin Cl. No. 45005*). For more delicate staining, dilute one part of the saturated solution with nine parts of acetone and prolong the time somewhat.
5. Clear directly in cedar oil, wash in xylene, and mount in terpene resin (Permount, HSR).

Results

Blue-green chromatin, red nucleoli, pink to red cytoplasm.

Stains for Hematologic Material and Air-Dried Smears

Wright's Stain

For identification of blood cells. Used by some for routine diagnostic purposes in FNA.

Components

Stock solution:

Wright's stain	0.5 g
Absolute methyl alcohol	100 ml

Working solution:

Wright's stain stock	25 ml
Buffer	75 ml

Buffer (pH 6.4):

KH ₂ PO ₄	6.63 g
Na ₂ HPO ₄	2.56 g
Distilled water	1,000 ml

Staining Procedure

1. Remove slides from 95% methyl alcohol and air-dry.
2. Flood slides with working solution of Wright's stain. Allow to stand until a metallic sheen appears (2-5 minutes).

3. Gently rinse slide with a stream of buffer from wash bottle to remove scum.
4. Rinse the slide under a thin stream of running tap water until thinner parts of smear turn pale purple or pinkish red.
5. Allow slide to dry. Dip dry slide in xylene and mount in gum damar in xylene or other suitable mounting medium.

Giemsa Stain

Components

Stock solution:

Azure II—eosin	2.0 g
Azure II	1.0 g
Azure B—eosin	1.0 g
Azure A—eosin	0.5 g

1. Mix 250 ml of glycerine with 250 ml of methyl alcohol.
2. Dissolve all dyes in this solution.
3. Let stand at room temperature overnight.
4. Shake mixture well for 5 to 10 minutes.
5. Pour, without filtering, into a dark screw cap bottle and store at room temperature.

Working solution:

1. Mix 5 ml of Giemsa stock solution and 65 ml of water.

Staining Procedure

Start with step 1 for paraffin sections and with step 8 for smears.

1. Xylol	5 minutes
2. Xylol	5 minutes
3. Absolute ethyl alcohol	15 dips
4. Absolute ethyl alcohol	15 dips
5. 95% Ethyl alcohol	15 dips
6. 80% Ethyl alcohol	15 dips
7. 70% Ethyl alcohol	15 dips
8. Wash in distilled water	15 dips
9. Giemsa working stain	2 hours
10. 1% Acetic acid	1 quick dip
11. Blot slide with bibulous paper	
12. 100% ethyl alcohol—until there is only a slight bluish tint to the alcohol that runs off the slide	
13. Xylene	10 dips
14. Xylene	10 dips
15. Mount with permanent mounting medium	

Wright-Giemsa Stain

Components

Wright's stain (see above).

Giemsa stain (see above).

Phosphate buffer (pH 6.8):

Potassium phosphate monobasic	7.32 g
Sodium phosphate dibasic anhydrous	2.8 g
Distilled water	100 ml

Staining Procedure

1. Remove slide from methyl alcohol and drain off excess alcohol.
2. Place slide horizontally on rack or flat surface.
3. Flood slide with Wright stain—3 minutes.
4. Flood slide with buffer—4 minutes. Mix the stain and
buffer by blowing gently on the slide. A metallic sheen appears.
5. Rinse slide well with tap water and drain off excess water.
6. Mix one drop of Giemsa with 1 ml of buffer. This must be fresh and made daily. Flood slide with this mixture for 20 minutes.
7. Rinse well with tap water.
8. Dehydrate smear with 10 dips in each of two 95% alcohols: one absolute alcohol and two xylenes.
9. Mount in permanent mounting medium.

P.1616

Modified May-Grünwald-Giemsa (MGG) Stain (Zajicek)

Routine staining for air-dried cytologic preparations (aspiration biopsy smears).

Components**May-Grünwald Reagent.****Stock solution** (keeps 2 weeks):

Eosin-methylene blue	1.0 g
Absolute methanol	100 ml

Working solution:

May-Grünwald stock	40 ml
Absolute methanol	20 ml

Giemsa Stain.**Stock solution:**

Azure II—eosin	0.6 g
Azure II Incubate at 37°C, 3h	0.16 g
Glycerin	50 ml
Absolute methanol	100 ml

Working solution:

Giemsa stock	10 ml
Distilled water	90 ml

Staining Procedure

1. May-Grünwald solution 5 minutes
2. Running water 1 minute
3. Giemsa solution 15 minutes

4. Running water 1 to 2 minutes
5. Air-dry. No mounting necessary

Results

Nuclei stain blue, cytoplasm stains pink to rose, and bacteria stain blue.

Stock solutions of May-Grünwald and Giemsa reagents are also commercially available from several manufacturers. Follow manufacturers' instructions to prepare working solutions. The staining procedure may vary somewhat and testing is recommended for optimal results.

Rapid Stains for Wet Sediment and Preliminary Examination of Aspiration Biopsies

As discussed at length in Chapter 28, these stains are used for rapid examination of aspiration smears at bedside. Some of these stains may also be used for final diagnosis. As suggested by Harris and Keebler (1976), these stains may also be used as: (1) a **control** when setting up new cytopreparatory procedures; (2) a **check on the cellular preservation of a sample**; (3) a method of identifying highly positive samples so they may be stained separately; and (4) a check on existing cytopreparatory methods.

Some observers recommend the use of these stains for diagnosis of fluid specimens, such as urine, effusions and spinal fluid. We have no experience with this application of rapid stains.

Three different stains are listed below. Any of them can be used, depending on individual preference.

Thionin Blue

Thionin blue Cl. No. 52000	1 g
25% Ethyl alcohol	100 ml
Glacial acetic acid	2 drops

Dissolve, let stand 30 minutes, filter, and store in a dark bottle. Frequent filtration and refrigeration are required.

Methylene Blue

Methylene blue-NF. Cl. No. 52015	1.5 g
95% Ethyl alcohol	30 ml
0.1 N potassium hydroxide	2 ml

Dissolve dye in the alcohol and add the potassium hydroxide. Store in dark bottles and refrigerate.

Toluidine Blue

Toluidine blue Cl. No. 52040	0.5 g
95% Ethyl alcohol	20 ml
Distilled water	80 ml

Dissolve dye in alcohol and add water. Filter and store in a dark bottle in the refrigerator.

For use with aspirated sample:

1. Fix the smear for at least 15 seconds in 70% to 95% ethanol or methanol.
2. Remove the slide from the fixative and place it on a paper towel.
3. Apply 1 or 2 drops of toluidine blue or one of the other two stains to the smear.
4. Cover the slide with a coverslip. After 10 to 15 seconds, blot out the excess stain by turning the coverslipped slide over on paper towels and pressing gently.
5. Examine the slide for adequacy of the specimen while it is still wet and, before it dries, return it to the fixative. The coverslip will easily fall off and the smear can be submitted without further preparation for Papanicolaou or hematoxylin-eosin stain.

For use with fluid specimens:

1. Place a drop of centrifuged specimen in the center of a glass slide and mix with an applicator

stick with a drop or two of dye.

2. Coverslip, making sure that the stained specimen is evenly spread on the slide.
3. Examine 2 to 5 minutes later.

If, for whatever reason, the slide is to be preserved, the coverslip can be sealed with petroleum jelly or, for permanent storage, with nail polish.

P.1617

Results

Methylene blue and toluidine blue stain all cells blue-purple, but distinct differences should be observed in the staining of the cytoplasm and the nucleus. In a well-differentiated preparation, the nucleoli are visible as more purple structures within the nucleus. Thionin blue gives similar results except that erythrocytes remain unstained.

Diff-Quik Stain

The Diff-Quik staining procedure is a rapid modification of Wright's stain (see above). The fixative and the two staining solutions are purchased in gallon (3.78 liters) containers (www.Fishersci.com). The staining procedure involves the following steps:

- | | |
|--|------------------|
| 1. Fixative | 20 seconds |
| 2. Staining solution I | 20 seconds |
| 3. Staining solution II | 20 seconds |
| 4. Distilled water | 10 seconds |
| 5. Ethanol 95% | 10 seconds |
| 6. Absolute ethanol | 15 seconds |
| 7. Xylene | 15 to 20 seconds |
| 8. Mount in Coverbond (American Scientific Products) | |

The results produced with Diff-Quik are similar to those obtained with Wright-Giemsa (see above) and can be used as either rapid or permanent stain. The smears stained with Diff-Quik are readily restained with Papanicolaou stain. No destaining is necessary. The Diff-Quik-stained smear is processed using **one-half the timing** for the routine Papanicolaou stain.

Stains for Flow Cytometry

As discussed in detail in Chapter 47, fluorescent stains (fluorochromes) have extensive application in flow cytometry. Such techniques may also be used for visual assessment of cells. There are numerous fluorochromes available for such studies. The two common ones are acridine orange (AO) and propidium iodide. Only dyes of the highest degree of purity should be used.

Acridine orange (Polyscience, Inc, Paul Valley Industrial Park, Warrington, PA) is a fluorochrome that changes color according to the state of nucleic acids. It fluoresces in green spectrum with double-stranded DNA and in red spectrum with single-stranded DNA or with RNA. The dye is finicky to use but has been applied in a number of investigative projects, discussed in Chapter 47.

Acridine Orange (AO)

A stock solution is prepared by dissolving 50 mg of purified AO in 50 ml of distilled water and stirring for 8 hours at room temperature in a dark glass flask, to prevent AO degradation by oxidation or light. This stock solution must be kept at 4°C in a tightly stoppered brown bottle, for not longer than 4 months. Prior to use, dilute the stock solution ten times and keep it cold. It should be used only on the day on which it is prepared. A working solution is made immediately before use by diluting further 17 ml of the diluted solution with up to 2 ml of TKM (*TKM solution: 50 mM Tris, pH 7.2; 25 mM KCl; 5 mM MgCl₂*). For AO staining, combine 1 ml of the final dilution of AO with a suspension of 2×10^5 cells in 1 ml of TKM, for a final AO concentration of 4.25×10^{-6} g/ml. Allow to equilibrate for 5 minutes at 25°C. All fluorescence measurements must be completed within ten minutes after staining. This procedure must be repeatedly tested by constructing concentration curves.

Propidium Iodide

Propidium iodide (PI) (Cal-Biochem, La Jolla, CA) is used for measurement of DNA in flow cytometry. This stain is considered a reliable indicator of DNA concentration and is less sensitive to environmental conditions than AO. A stock solution containing 250 mg of PI in 100 ml of distilled water is prepared. This mixture is stirred at room temperature until dissolved and then stored in a dark brown bottle at 4°C. The unused solution is discarded after 6 months. A working solution is prepared by diluting the stock solution 50 times with 0.1% sodium citrate.

The cells are stained with PI by resuspending 1×10^5 cells in 1 ml of PI working solution. The cells are allowed to stand for at least 5 minutes but not more than 15 minutes at 4°C before fluorescence measurements. In the Appendix to Chapter 47, several modifications of this stain are discussed.

SPECIAL TECHNIQUES

Special techniques have been devised for isolation of cells from very small samples.

Sedimentation Technique for Cerebrospinal Fluid*

This technique is based on the principle of slow absorption of fluid by hard filter paper. If the absorption is very slow, the cells will sink to the slide placed beneath. The absorption is slowed down by placing heavy weights on the filter paper.

Apparatus

The apparatus can be constructed in a machine shop (Fig. 44-16).

- Slide holder
- Tube holder
- Weights
- Glass tube 15 mm in diameter and 20 mm high
- Filter paper (Green 602 or Schleicher and Schöll 602 hard is acceptable)

Procedure

Approximately 1 ml of fresh cerebrospinal fluid is placed in a small glass tube 15 mm in diameter and 20 mm high. The open end of the tube is placed against a glass slide covered with a piece of filter paper (see Fig. 44-16). The paper is perforated and the size of the hole corresponds to

P.1618

the internal diameter of the tube. Place tube within the hole. The cells sink to the bottom of the tube and settle on the slide and the fluid portion of the specimen is slowly absorbed by the filter paper. A large percentage of the cell is absorbed by the paper at the beginning of sedimentation, if the filter paper is completely dry. This can be partially prevented by passing 0.5 ml of saline solution through the tube before introducing the cerebrospinal fluid.

Figure 44-16 Apparatus for sedimentation technique for spinal fluid. *Top.* Cross-section of the apparatus. *A.* Glass slide. *B.* Filter paper. The rate of fluid absorption is regulated by weights, placed on top of the rubber block *C.* *C.* Rubber block with a hole accommodating a glass tube filled with spinal fluid. *D.* Glass tube with open end resting on glass slide. *Bottom.* View of the apparatus from above. Parts are as above. *E.* Adjustable weights. The pressure is transmitted via the rubber block *C* and regulates the rate of fluid absorption by the filter paper (*B*). (After Bots GT, Went LN, Schaberg A. Results of sedimentation technique for cytology of cerebrospinal fluid. *Acta Cytol* 8:234-241, 1964.)

To regulate the rate of sedimentation and to limit the loss of cells, the glass tube is placed in a block of rubber in which a hole has been bored. Attachment of adjustable weights to the rubber block allows control of speed of fluid absorption. A weight of 3 kg applied on the correct filter paper results in sedimentation of 1 ml of cerebrospinal fluid with a normal protein content in approximately 25 minutes.

When the protein content of the cerebrospinal fluid is high, the rate of sedimentation is slower. If the quantity of fluid is not appreciably decreased in approximately 30 minutes, the weights on the lever must be adjusted to reduce the pressure. Sedimentation time of less than an hour can be achieved fairly consistently by the use of this procedure. After sedimentation is complete, the preparation is allowed to dry. The cells may be stained by the Giemsa or other methods.

The disadvantage of this method lies in cell distortion due to drying. However, if proper adjustment is made to prevent this, excellent diagnostic results can be achieved.

Results

Bots et al (1964) reported that malignant cells were detected cytologically in 16 of 31 cases with histologically confirmed tumors or leukemias affecting the central nervous system. Identification of tumor type was possible in 13 of the 16 positive cases.

Excellent results with an essentially similar method were reported by Eneström (1965).

Pasteur Pipette Method

This method (developed by G.R. Durfee, G. Welborne, and L.G. Koss) can be used advantageously for cerebrospinal fluid and other fluids with sparse cell population (Fig. 44-17).

Materials

1. Prepare microcentrifuge tubes by cutting off tops of 5¼-inch Pasteur pipettes at indentation, so that final length of the tube is 4¾ inches. Flame tip of tube to close opening.
2. Nine-inch disposable Pasteur pipettes with standard dropper bulb for transfer of fluid specimen or for removal of supernatant fluid.
3. Clinical centrifuge (International Equipment Company, Needham, MA) with 4-place No. 215 horizontal head, trunnion rings, and shields for accommodating 50-ml tubes. Use cylindrical rubber blocks (International Equipment Company) that fit shields and extend 1/16 inch above lip of shield. The blocks are bored to accommodate five of the above constructed microtubes. Each block is grooved slightly the entire length of one side to facilitate removal if a tube breaks and liquid seeps between shield and block, creating undue suction.
4. Slides covered with Mayer's albumin or other adhesive.

Procedure

Place closed-tip microtube in bored rubber blocks. Mix specimen thoroughly. Transfer fluid into each tube with 9-inch Pasteur pipette with bulb. Place tip of transfer pipette into tube as far as narrowed portion and gently drop specimen while withdrawing pipette slowly. Fill to a half inch from the top of microtube. Balance and centrifuge at approximately 200 rpm for 30 minutes.

After centrifugation, gradually remove supernatant fluid with 9-inch pipette by starting from top and using gentle suction as narrow portion of tube is approached. Care must be taken not to suck up specimen button formed at tip. A few drops of liquid will remain in tip over specimen button. Lay tip of microtube on an adhesive-coated slide and cut

P.1619

off tip with a vial file below button. The few drops of liquid left in the tip of microtube are usually sufficient to expel the button onto slide. If the button is not expelled, place dropper bulb on microtube and gently force out. Smear button on albuminized slide with tip of microtube and dry in air for 5 to 10 seconds before placing in fixative (95% ethyl alcohol). Occasionally, spinal fluids are clear and will not yield a visible button after centrifugation. In these instances, make smears of the few drops of fluid remaining in the tip of tube. Stain by the routine Papanicolaou method.

Figure 44-17 Pasteur pipette method for small amounts of fluid. A. Pasteur pipette with tip flamed off. The top should be cut at indentation (arrow). B. Full-length Pasteur pipette with rubber dropper bulb used for transfer of fluid or for removal of supernatant fluid. C. Pasteur pipette cut to size with tip flamed, filled with fluid to be processed. D. Rubber block accommodating five pipettes and fitting into centrifuge shield. E. The groove in the rubber block facilitates removal. F. Pipette with fluid placed in rubber block within the centrifuge shield. G. Pipette after centrifuge. The sediment is shown as a black deposit at bottom of the tube.

The principle of separation and enrichment of a specific cell population in a fluid by flotation techniques is based on documented **differences in specific gravity (SG)**. Red blood cells have an SG of 1.092 to 1.097; leukocytes have an average SG of about 1.065, and cancer cells average 1.056 (Seal, 1959). Several flotation techniques, using various media of cell separation, have been developed and used with varying degrees of success for separation of cancer cells in fluids and the circulating blood. In general, the methods achieve good concentration of cells in fluids, but their preservation is not optimal. Seal (1959) devised a cumbersome, but effective, method using a solution of blended silicone with a specific gravity of 1.075 which serves as a separating medium. Ideally, cancer cells and lymphocytes should accumulate on the surface of the silicone, whereas the heavier erythrocytes and polymorphonuclear leukocytes should collect under the silicone. Albumin with a known specific gravity can also be used, as described below (McGrew and Nanos, 1976).

Preparation of Solutions

Solution A:

Patho-o-cyte 2 (25%)*	4 ml
Physiologic saline solution	1 ml

or

Solution B:

Patho-o-cyte 3* (30%)	3.5 ml
Physiologic saline solution	1.5 ml

* *Albumin solution available from Miles Laboratories, Inc., Elkhart, IN.*

1. The specimen must be collected in an anticoagulant and should not contain clots. Centrifuge sample and prepare sediment smears as described by one of the methods above.
2. Resuspend remaining sediment in 5 ml of the original fluid.
3. Place 5 ml of Solution A or B (see above) in a 10-ml plastic tube.
4. Carefully layer 5 ml of the original or resuspended sample over the albumin suspension. Avoid mixing the two solutions.
5. Carefully balance the tube and centrifuge at 2,500 rpm for 10 minutes. Allow the centrifuge to come to a complete stop. *Do not use brake.*
6. Aspirate with a syringe and an 18-gauge needle with the bevel filed off and the layer of cells floating at the interphase of the albumin and sample (Fig. 44-18).
7. Resuspend this layer of cells in a balanced salt solution, centrifuge, and prepare slides by one of the methods described previously.

P.1620

Other Flotation Techniques

Besides albumin and silicone gradients, other materials have been recommended for the same purpose. Many of the solutions used were originally developed for other purposes. The solutions are commercially produced and highly standardized.

Ficoll Method

The Ficoll-Trisil method was initially introduced by Böyum in 1968 for separation of lymphocytes from the blood. Ficoll is a cross-linked polymerized sucrose. Eloquin et al (1977) advocated the use of Ficoll (www.amersham-biosciences.com) gradient of SG 1.050 to 1.052 for isolation of cancer cells from cell suspensions, followed by the use of a cytocentrifuge for preparation of cell spreads. The centrifuged sample contained a clear band of cancer cells and leukocytes that could be removed by pipette and placed in the cytocentrifuge well. Although good concentration of cancer cells was obtained, the preservation of the cells on the slide was not optimal.

Hypaque (Sodium Diatrizoate) Technique

Spriggs (1975) advocated the use of 25% Hypaque solution (Sterling Organics, Division of Sterling Drug, New York, NY), originally used as an intravenous contrast medium in radiography, for separation of erythrocytes from bloody fluids. The fluids are collected with

EDTA (2 mg per ml of fluid) to prevent coagulation. After initial centrifugation of fluid to produce a cell button (time and speed are not critical), the gradient is prepared in a round-bottom centrifuge tube by mixing about 4 ml each of Hypaque solution and supernatant fluid. The remaining supernatant is discarded. The cells from the hemorrhagic button from the original fluid are gently mixed and layered on top of the gradient. The mixture is centrifuged for 15 minutes at 3,000 rpm. The erythrocytes are at the bottom of the tube and the white cells above. The white cells are removed with a pipette and a smear is prepared, either directly or after further centrifugation. The method offers good concentration of cancer cells, but their preservation is not optimal.

DIGESTION OF LUNG TISSUE OR SPUTUM FOR THE DETECTION OF FERRUGINOUS (ASBESTOS) BODIES

Materials

- Laundry bleach, such as Clorox, which is a 5.25% solution of sodium hypochlorite
- 300- to 500-ml glass containers
- Chloroform
- 50% Ethyl alcohol
- 50-ml centrifuge tubes
- 95% Ethyl alcohol
- Nuclepore filters, 8 to 12 μ m pore size, and filtering setup

Procedure

This technique (developed by Smith and Naylor, 1972) may be used for lung tissue or sputum samples. However, the sputum is digested in a matter of minutes, whereas tissue samples require 24 hours or more.

1. Select approximately 5 g of pulmonary parenchyma from a fresh or fixed lung. Avoid bronchi, bronchioles, large blood vessels, and areas of consolidation.
2. Cut lung tissue into small pieces.
3. Place the pieces of lung or sputum into a glass jar and add approximately 200 ml of bleach. If greater than 5 g of lung is to be digested, increase the amount of bleach proportionately.

P.1621

4. Let the pieces of lung stay in this solution until the *entire* sample is dissolved. This may require 24 to 72 hours. If the tissue is not completely dissolved in 24 hours, pour off the supernatant and add fresh bleach. This step should be repeated every 24 hours until digestion is complete. Sputum liquefies immediately. However, several hours may be required if one wishes to completely remove all cellular structures.

5. Carefully decant the bleach without disturbing or losing any of the sediment.

6. Add 20 ml of chloroform to the jar. Swirl it around to clean the sides of the jar. Then add 20 ml of 50% ethyl alcohol and shake the jar vigorously to suspend all sediment.

7. Centrifuge this mixture in 50-ml centrifuge tubes for 10 minutes at 600 to 800 rpm.

Three visible layers should appear:

Top layer: alcohol

Middle layer: carbonaceous material

Bottom layer: chloroform

8. Pour off the supernatant. If a visible black, gray, or golden sediment remains in the tip of the tube, repeat steps 6 and 7 until there is no visible sediment.

9. Add 95% ethyl alcohol to the centrifuge tube and mix well.

10. Filter this solution through a Nuclepore filter. Using 95% alcohol, wash the centrifuge tube out several times and wash down the sides of the funnel.

11. After allowing all the fluid to pass through the filter, let the filter dry out for 10 to 15 seconds before turning off the vacuum.

12. Place the completely dry, *unstained filter*, sediment side down, on a coverslip.

13. Place the coverslip on a flat surface, flood it with chloroform, and let the chloroform evaporate completely.

14. Dip the dry coverslip into xylol and mount it onto a glass slide.

Quantitation of Asbestos Bodies

The method can be used for quantitation of ferruginous bodies per gram of material. If this is the purpose, several filters may have to be used for each specimen to facilitate counting.

FLUORESCENT IN SITU HYBRIDIZATION (FISH)

This technique has found wide application in detection of numerical chromosomal abnormalities, using either whole chromosome "paint" probes or probes to centromeres of specific chromosomes. The technique can also be used to detect products of chromosomal translocation using specific probes.* The principles of the technique are explained in Chapter 3 and its applications in Chapter 4. Diagnostic applications of this technique to specimens of urine, effusions, sputum or bronchial washings, and lymph node aspirates are discussed in Chapters 20, 26, 31, and 45.

Equipment

- Microscope slides
- Glass coverslips, 18 × 18 mm
- Water bath
- Coplin jars (glass)
- Micropipettors, sizes: 10 µl, 100 µl
- Micropipettor tip, sizes: 10 µl, 100 µl
- Fluorescent microscope
- Incubator at 37°C
- Bucket of crushed ice
- Light tight incubation box with tape
- Microcentrifuge
- Vortex mixer
- 100 ml graduated glass cylinders

Reagents

1. Freshly made fixative—modified Carnoy's fixative—see below.
2. 20 × Saline Sodium Citrate (SSC) (1 × = 0.15 M NaCl, 0.015 M Na Citrate)
3. Ethanol (two sets)
 - a. 70%, 80%, 90% and 100% (v/v) in Coplin jars at room temperature
 - b. 70%, 80%, 90% and 100% (v/v) in Coplin jars on ice
4. Choice of probes:
 - a. Whole Chromosome Paint—DNA Probes
 - b. Chromosome Enumeration—DNA Probes—satellite
 - c. Locus Specific Identifier—DNA Probes

5. Hybridization buffer
6. Formamide
7. Rubber cement
8. Phosphate, Nonidet P-40 buffer (PN): 93.2 mM Na₂ HPO₄, 6.8 mM NaH₂ PO₄, Nonidet P-40 0.1% (v/v), pH 7.4
9. Vectashield mounting medium for fluorescence with DAPI (Vector Laboratories, Inc, Burlingame, CA)
10. Nail polish

Modified Carnoy's Fixative for Fluorescent In Situ Hybridization (FISH)

Absolute methanol 45 ml

Glacial acetic acid 15 ml

Mix in a beaker and transfer to another container, if needed. The fixative is immediately ready for use. Keep at room temperature. Discard after 2 to 5 days. This fixative is also optimal **for rapid fixation of fresh cells in smears**. Place the slide on a flat surface and, with a pipette, place enough of the fixative to generously cover the target area. Fix for a minimum of 15 minutes, adding drops of fixative to compensate for evaporation. Place the fixed slide in a container with a tight lid and keep at - 4°C. The fixed slide can be kept for many months before use.

P.1622

Protocol***Cell Fixation***

1. Rinse slides in three changes of phosphate buffered saline (PBS).
2. Fix slides in freshly prepared fixative in a Coplin jar for 10 minutes at room temperature (RT).
3. Air dry slides for 10 minutes at RT.
4. Wash in three changes of PBS for 1 minute each at RT.
5. Air-dry for 10 minutes.
6. Proceed with FISH or store desiccated slides at - 20°C.

Slide Preparation

1. Incubate slides overnight at 37°C.
2. Wash slides in 2 × SSC, pH 7.0 at 37°C for 30 minutes.
3. Dehydrate slides in 70%, 80%, 90%, and 100% ethanol at room temperature for 2 minutes each.
4. Air-dry.
5. Denature the DNA on the slides in 70% formamide, 2 × SSC at 70°C for 2 minutes.
6. Dehydrate the slides in 70%, 80%, 90%, and 100% ethanol at 4°C for 2 minutes each.
7. Air-dry.

Probe Preparation

Fluorophores are readily bleached in direct light so work under reduced light conditions for all further steps.

1. Warm probes and hybridization buffer to room temperature, vortex, then centrifuge briefly.
2. For each half slide, mix 7 µl of hybridization buffer, 1 µl of probe, and 2 µl distilled H₂O.
3. Vortex, then centrifuge briefly.
4. Heat in a 73°C water bath for 5 minutes.
5. Put directly on ice for 5 minutes.
6. Vortex, centrifuge again for 1 minute.

Hybridization

1. Apply 10 µl of probe mix to half a slide or 20 µl to a full slide.

2. Place an 18 × 18 mm glass coverslip on slide and seal with rubber cement.
3. Place slide in a humidified box and seal box with tape to make it light tight.
4. Incubate box at 37°C overnight.

Post-Hybridization Washes

1. Remove rubber cement seal and coverslip.
2. Wash slide in 1 × SSC, pH 7.0 at 70°C for 5 minutes.
3. Wash slide 3 times in PN buffer at room temperature for 2 minutes each, gently agitating the slide for 5 seconds.
4. Air-dry for 10 minutes.
5. Counterstain with Vectashield Mounting Medium for Fluorescence with DAPI.
6. Place glass coverslip and seal edges with nail polish.
7. Store slides at - 20°C protected from light.

A somewhat different procedure was recommended by Vysis, Inc. (Abbott-Vysis, Downers Grove, IL). The interested reader should write to the company for details of the procedure.

FISH can also be performed using a HYBrite Denaturation/Hybridization System, which handles 12 slides. It can be purchased from Vysis.

For a discussion of immunocytologic techniques, see Chapter 45.

PRINCIPLES OF OPERATION OF A LABORATORY OF CYTOLOGY

LABORATORY SAFETY

Chemical, electrical, fire, and infectious hazards are of paramount concern for all individuals working in the cytopreparatory laboratory. It is imperative that all personnel thoroughly understand the procedures to follow in case of emergencies and the methods used to minimize the possibility of accidents and infection. State and federal agencies that license or inspect laboratories require that safety standards and regulations be met. Guidelines for the preparation of a detailed safety manual are listed in this section. References listed at the conclusion of the chapter may be consulted for further details.

Every employee should know the location of:

- Fire extinguishers
- Fire blankets
- Fire alarm and emergency exits
- Eye wash equipment
- Safety shower

Every employee should know the correct procedures to follow for:

- Chemical splash to the eye or body
- Fire, explosion, or electrical shock
- Storage, handling, disposal, and emergency treatment necessary for all chemicals used in the laboratory
- Handling and disposal of potentially infectious material

Guidelines for Storing and Handling Chemicals and Electrical Equipment

1. Store chemicals in their original containers, if possible, or in appropriate chemical-resistant plastic containers.
2. A cool, well-ventilated metal cabinet or closed room should be used to store volatile, flammable, and explosive materials.
3. Appropriate fire-fighting equipment should be in the immediate area.
4. Do not transfer chemicals with a pipette in the mouth. Use pumps for transferring large volumes and a bulb pipette for small volumes.
5. Volatile, toxic, or irritating chemicals should be transferred under a fume hood.
6. Label all laboratory reagents with date of preparation or delivery and attach poison sticker where indicated (Table 44-14).

7. When diluting solutions, always add the concentrated chemical to the water.

P.1623

8. Never smoke or eat in an area where chemicals are stored or in use.
9. Wear safety glasses when working with caustic chemicals.
10. Wash hands after handling any chemical.
11. Staining and coverslipping should take place in a well-ventilated area or under a fume hood.
Avoid inhaling vapors during these procedures.
12. Make certain that all electrical equipment is grounded properly.
13. Never handle electrical switches or controls with wet hands.

TABLE 44-14 ESSENTIAL SAFETY-RELATED PROPERTIES OF SOME COMMON CHEMICALS USED IN CYTOPREPARATORY LABORATORIES

Name of Chemical	Properties	Maximum Permissible Atmospheric Concentration	Symptoms of Poisoning
Acetone	* Flash point - 17°C Highly inflammable	1000 ppm [†]	Inhalation or ingestion: Pulmonary congestion with edema, dyspnea, decreased respirations, and stupor
Concentrate acids or alkali			Corrosive burns
Alcohol			
Ethyl	Flash point 14°C Readily inflammable	1000 ppm	Stupor, flushing, nausea, and vomiting
Isopropyl	Flashpoint 12°C Inflammable	400 ppm	Stupor, coma, hypotension. 8 oz. (240 ml) probably fatal.
Methyl	Flash point 10°C Inflammable	200 ppm	May be fatal, decreased respiration, vertigo, dimness of vision, headache, convulsions; may lead to loss of vision
Ammonium hydroxide (concentrated)	Fumes formed when bottles are near volatile acids. Becomes boiling hot in reaction with H ₂ SO ₄	50 ppm	Corrosive burns from eye and skin contact, inhalation, and ingestion
Chloroform	Nonflammable: Forms toxic gas when in contact with heat	25 ppm	Drowsiness, coma - irritant to skin and mucous membranes

Ether	Flash point - 29°C Mixed with air can cause explosions. Store in airtight containers in a cool (8-15°C) place away from sparking apparatus. Do not refrigerate (<8°C).	400 ppm	Exerts a narcotic action somewhat similar to alcohol. Irritant to skin and mucous membranes
Formalin	Flash point 60°C Should be stored in a well-closed container in a moderately warm place	-	Irritant to skin and mucous membranes, contact dermatitis, bronchitis, and occasionally asthmatic attack
Xylene	Flash point 4°C	100 ppm	Dizziness, weakness, headache, nausea, vomiting, euphoria, ventricular arrhythmia, convulsions

* Flash point: The lowest temperature at which vapors above a volatile combustible substance ignite in air when exposed to flame.

† Parts per million.

Infectious Hazards

With the growing concern of exposure to AIDS in the workplace, it is necessary to emphasize the need to treat blood and body fluids from *all* patients as potentially infective. The Centers for Disease Control estimated that 1.5 to 2

P.1624

million individuals seropositive for human immunodeficiency virus (HIV) in the United States in 1991 quadrupled by 1995. All specimens, including the outside of the specimen jar, should be considered contaminated with potentially infectious organisms. Infections may occur from direct contact or from inhaling aerosols created by centrifuging, blending, stirring, and pouring. Written procedures should be a part of the standard operating manual of each laboratory.

The following are excerpts applicable to the laboratory from [No Author]. Recommendations for Prevention of HIV Transmission in Healthcare Setting. MMWR Morb Mortal Wkly Rep 36:1S-18S, 1987.

Precautions to Prevent Transmission of Human Immunodeficiency Virus (HIV)

Universal Precautions

Since medical history and examination cannot reliably identify all patients infected with HIV or other blood-borne pathogens, blood and body-fluid precautions should be consistently used for *all* patients. This approach, previously recommended by CDC, referred to as "universal blood and body-fluid precautions" or "universal precautions," should be used in the care of *all* patients, especially including those in emergency care settings in which the risk of blood exposure is increased and the infection status of the patient is usually unknown.

1. All healthcare workers should routinely use appropriate barrier precautions to prevent skin and mucous-membrane exposure when contact with blood or other body fluids of any patient is anticipated. Gloves should be worn for touching blood and body fluids, mucous membranes, or nonintact skin of all patients, for handling items or surfaces soiled with blood or body fluids, and for performing venipuncture and other vascular access procedures. Gloves should be changed after contact with each patient. Masks and protective eyewear or

face shields should be worn during procedures that are likely to generate droplets of blood or other body fluids to prevent exposure of mucous membranes of the mouth, nose, and eyes. Gowns or aprons should be worn during procedures that are likely to generate splashes of blood or other body fluids.

2. Hands and other skin surfaces should be washed immediately and thoroughly if contaminated with blood or other body fluids. Hands should be washed immediately after gloves are removed.
3. All healthcare workers should take precautions to prevent injuries by needles, scalpels, and other sharp instruments or devices during procedures; when cleaning used instruments; during disposal of used needles; and when handling sharp instruments after procedures. To prevent needlestick injuries, needles should not be recapped, purposely bent or broken by hand, removed from disposable syringes, or otherwise manipulated by hand. After they are used, disposable syringes and needles, scalpel blades, and other sharp items should be placed in puncture-resistant containers for disposal; the puncture-resistant containers should be located as close as practical to the use area. Large-bore reusable needles should be placed in a puncture-resistant container for transport to the reprocessing area.
4. Although saliva has not been implicated in HIV transmission, to minimize the need for emergency mouth-to-mouth resuscitation, mouthpieces, resuscitation bags, or other ventilation devices should be available for use in areas in which the need for resuscitation is predictable.
5. Healthcare workers who have exudative lesions or weeping dermatitis should refrain from all direct patient care and from handling patient-care equipment until the condition resolves.
6. Pregnant healthcare workers are not known to be at greater risk of contracting HIV infection than healthcare workers who are not pregnant; however, if a healthcare worker develops HIV infection during pregnancy, the infant is at risk of infection resulting from perinatal transmission. Because of this risk, pregnant healthcare workers should be especially familiar with, and strictly adhere to, precautions to minimize the risk of HIV transmission.
7. Implementation of universal blood and body-fluid precautions for *all* patients eliminates the need for use of the isolation category of "Blood and Body Fluid Precautions," previously recommended by CDC for patients known or suspected to be infected with blood-borne pathogens. Isolation precautions (e.g., enteric, acid-fast bacteria) should be used as necessary if associated conditions, such as infectious diarrhea or tuberculosis, are diagnosed or suspected.

Precautions for Laboratories

Blood and other body fluids from *all* patients should be considered infective. To supplement the universal blood and body-fluid precautions listed above, the following precautions are recommended for healthcare workers in clinical laboratories.

1. All specimens of blood and body fluids should be put in a well-constructed container with a secure lid to prevent leaking during transport. Care should be taken when collecting each specimen to avoid contaminating the outside of the container and of the laboratory form accompanying the specimen.
2. All persons processing blood and body-fluid specimens (e.g., removing tops from vacuum tubes) should wear gloves. Masks and protective eyewear should be worn if mucous-membrane contact with blood or body fluids is anticipated. Gloves should be changed and hands washed after completion of specimen processing.
3. For routine procedures, such as histologic and pathologic studies or microbiologic culturing, a biological safety cabinet is not necessary. However, biological safety cabinets (class I or II) should be used whenever procedures are conducted that have a high potential

P.1625

for generating droplets. These include activities such as blending, sonicating, and vigorous mixing.

4. Mechanical pipetting devices should be used for manipulating all liquids in the laboratory. Mouth pipetting is no longer acceptable.
5. Use of needles and syringes should be limited to situations in which there is no alternative, and the recommendations for preventing injuries with needles outlined under universal precautions should be followed.
6. Laboratory work surfaces should be decontaminated with an appropriate chemical germicide after a spill of blood or other body fluids and when work activities are completed.

7. Contaminated materials used in laboratory tests should be decontaminated before reprocessing or be placed in bags and disposed of in accordance with institutional policies for disposal of infective waste.
8. Scientific equipment that has been contaminated by blood or other body fluids should be decontaminated and cleaned before being repaired in the laboratory or transported to the manufacturer.
9. All persons should wash their hands after completing laboratory activities and should remove protective clothing before leaving the laboratory.
10. Implementation of universal blood and body-fluid precautions for *all* patients eliminates the need for warning labels on specimens since blood and other body fluids from all patients should be considered infective.

Environmental Considerations for HIV Transmission

No environmentally mediated mode of HIV transmission has been documented. Nevertheless, the precautions described below should be taken routinely in the care of *all* patients.

Sterilization and Disinfection

Standard sterilization and disinfection procedures for patient-care equipment currently recommended for use in a variety of healthcare settings—including hospitals, medical and dental clinics and offices, hemodialysis centers, emergency-care facilities, and long-term nursing-care facilities—are adequate to sterilize or disinfect instruments, devices, or other items contaminated with blood or other body fluids from persons infected with blood-borne pathogens including HIV.

Instruments or devices that enter sterile tissue or the vascular system of any patient or through which blood flows should be sterilized before reuse. Devices or items that contact intact mucous membranes should be sterilized or receive high-level disinfection, a procedure that kills vegetative organisms and viruses but not necessarily large numbers of bacterial spores. Chemical germicides that are registered with the US Environmental Protection Agency (EPA) as “sterilants” may be used either for sterilization or for high-level disinfection depending on contact time.

Contact lenses used in trial fittings should be disinfected after each fitting by using a hydrogen peroxide contact lens disinfecting system or, if compatible, with heat (78°C to 80°C [172.4°F to 176.0°F]) for 10 minutes.

Medical devices or instruments that require sterilization or disinfection should be thoroughly cleaned before being exposed to the germicide, and the manufacturer's instructions for the use of the germicide should be followed. Further, it is important that the manufacturer's specifications for compatibility of the medical device with chemical germicides be closely followed. Information on specific label claims of commercial germicides can be obtained by writing to the Disinfectants Branch, Office of Pesticides, Environmental Protection Agency, 401 M Street, SW, Washington DC, 20460.

Studies have shown that HIV is inactivated rapidly after being exposed to commonly used chemical germicides at concentrations that are much lower than used in practice. Embalming fluids are similar to the types of chemical germicides that have been tested and found to completely inactivate HIV. In addition to commercially available chemical germicides, a solution of sodium hypochlorite (household bleach) prepared daily is an inexpensive and effective germicide. Concentrations ranging from approximately 500 ppm (1:100 dilution of household bleach) sodium hypochlorite to 5,000 ppm (1:10 dilution of household bleach) are effective depending on the amount of organic material (e.g., blood, mucus) present on the surface to be cleaned and disinfected. Commercially available chemical germicides may be more compatible with certain medical devices that might be corroded by repeated exposure to sodium hypochlorite, especially to the 1:10 dilution.

Survival of HIV in the Environment

The most extensive study on the survival of HIV after drying involved greatly concentrated HIV samples, i.e., 10 million tissue-culture infectious doses per milliliter. This concentration is at least 100,000 times greater than that typically found in the blood or serum of patients with HIV infection. HIV was detectable by tissue-culture techniques 1 to 3 days after drying, but the rate of inactivation was rapid. Studies performed at CDC have also shown that drying HIV causes a rapid (within several hours) 1-2 log (90% to 99%) reduction in HIV concentration. In tissue-culture fluid, cell-free HIV could be detected up to 15 days at room temperature, up to 11 days at 37°C (98.6°F), and up to 1 day if the HIV was cell-associated.

When considered in the context of environmental conditions in healthcare facilities, these results do not require any changes in currently recommended sterilization, disinfection, or housekeeping strategies. When medical devices are contaminated with blood or other body fluids, existing recommendations include the cleaning of these instruments, followed by disinfection or sterilization, depending on the type of medical device. These protocols assume "worst-case" conditions of extreme virologic and microbiologic contamination, and whether viruses have been inactivated after drying plays no role in formulating these strategies. Consequently, no changes in published procedures for cleaning, disinfecting, or sterilizing need to be made.

P.1626

Housekeeping

Environmental surfaces such as walls, floors, and other surfaces are not associated with transmission of infections to patients or healthcare workers. Therefore, extraordinary attempts to disinfect or sterilize these environmental surfaces are not necessary. However, cleaning and removal of soil should be done routinely.

Cleaning schedules and methods vary according to the area of the hospital or institution, type of surface to be cleaned, and the amount and type of soil present. Horizontal surfaces (e.g., bedside tables and hard-surface flooring) in patient-care areas are usually cleaned on a regular basis, when soiling or spills occur, and when a patient is discharged. Cleaning of walls, blinds, and curtains is recommended only if they are visibly soiled. Disinfectant fogging is an unsatisfactory method of decontaminating air and surfaces and is not recommended.

Disinfectant-detergent formulations registered by EPA can be used for cleaning environmental surfaces, but the actual physical removal of microorganisms by scrubbing is probably at least as important as any antimicrobial effect of the cleaning agent used. Therefore, cost, safety, and acceptability by housekeepers can be the main criteria for selecting any such registered agent. The manufacturers' instructions for appropriate use should be followed.

Cleaning and Decontaminating Spills of Blood or Other Body Fluids

Chemical germicides that are approved for use as "hospital disinfectants" and are tuberculocidal when used at recommended dilutions can be used to decontaminate spills of blood and other body fluids. Strategies for decontaminating spills of blood and other body fluids in a patient-care setting are different than for spills of cultures or other materials in clinical, public health, or research laboratories. In patient-care areas, visible material should first be removed and then the area should be decontaminated. With large spills of cultured or concentrated infectious agents in the laboratory, the contaminated area should be flooded with a liquid germicide before cleaning then decontaminated with fresh germicidal chemical. In both settings, gloves should be worn during the cleaning and decontaminating procedures.

Laundry

Although soiled linen has been identified as a source of large numbers of pathogenic microorganisms, the risk of actual disease transmission is negligible. Rather than rigid procedures and specifications, hygienic and common-sense storage and processing of clean and soiled linen are recommended. Soiled linen should be handled as little as possible and with minimum agitation to prevent gross microbial contamination of the air and of persons handling the linen. All soiled linen should be bagged at the location where it was used; it should not be sorted or rinsed in patient-care areas. Linen soiled with blood or body fluids should be placed and transported in bags that prevent leakage. If hot water is used, linen should be washed.

Special Precautions for Operation of a Cytopreparatory Laboratory

Notwithstanding the general rules summarized above, certain procedures that are specific for a cytopreparatory laboratory must be observed.

1. Laboratory request slips accompanying specimen should not be wrapped around the specimen containers. The slips should be removed and placed in an area away from the preparation counter.
2. Prepare specimens in a room or area away from other work areas.
3. Process all specimens under a laminar flow hood. Disposable gloves, gowns, aprons, and face paper masks must be worn, particularly if there is a possibility of a spray of droplets (for example, blending of sputum). Remove such attire before leaving the laboratory and dispose of it in containers for infectious waste. Staining of specimens, however, may be performed in an open, well-ventilated area and does not require a laminar flow hood.
4. Cover the counter of the working area with absorbent paper toweling moistened with a

disinfectant.

5. Inspect centrifuge tubes for cracks. Use disposable screw-cap plastic centrifuge tubes. Never centrifuge or vortex in an open tube. Add a germicidal solution (1:10 dilution of 5.25% sodium hypochlorite [bleach]) between the centrifuge tube and trunnion cup.
6. Cytocentrifuge chambers must be decontaminated with germicidal solution.
7. Never pipette samples by mouth.
8. Develop the habit of keeping your hands away from your mouth, nose, eyes, and face.
9. Wash hands thoroughly after handling any specimen, including the outside of the specimen jar.
10. Discard needles into a special needle disposal container and residual fluids into an autoclaveable, splashproof container containing a small amount of disinfectant. Autoclave the container before disposing of the contents.
11. Contaminated equipment should be autoclaved before washing or disposal. Preferably this should be done in the laboratory area. If this is not possible, the material should be placed in a leak-proof plastic bag and sealed. The sealed bag should be placed inside a leak-proof autoclaveable pail with a cover.
12. Laboratory benches, work counters, and all surfaces where infectious material is handled should be disinfected after completion of specimen preparation.
13. Equipment used in the cytopreparation laboratory should not be used in other areas of the laboratory.
14. Limit the flow of traffic into and out of the cytopreparation area.
15. Never smoke, eat, or drink in the cytopreparatory laboratory.

SCREENING AND MARKING OF SMEARS

Slides are placed in the mechanical stage holder of the microscope with the label *always* on the same side, either left

P.1627

or right. The slides are best screened vertically, and there should be a slight overlapping of the screened areas so that no cells will be missed (Fig. 44-19). Although some individuals prefer to screen cytologic slides horizontally, this procedure may produce visual fatigue, since any optical aberrations in the glass slide or the cover glass are more noticeable and annoying. For screening, we recommend a 10 × objective lens and 10 × or 15 × ocular lenses. This optical system will ensure optimal evaluation of small cells. For detailed examination of cells, a 40 × objective lens should be used. Oil immersion is of limited use in diagnostic cytology.

Figure 44-19 Diagram of correct screening of smears. A slight overlap of the fields of vision ensures that no important evidence is overlooked.

When marking cells, switch to a scanning lens and, using a pen with a fine point, place an ink dot next to the cell. The position of this mark in relation to the cells in question *should always be the same* (Fig. 44-20). A circle may be placed around the cells in the same way. A short time is required to master the technique of coordinating the hand while looking through the microscope.

The importance of proper screening of slides needs to be emphasized. Marking of slides will facilitate the examination of the same cell or group of cells on multiple occasions or by several

observers. Proper screening and marking of slides are indispensable in a well organized cytology laboratory.

ORGANIZATION OF THE CYTOLOGY LABORATORY

Federal and state agencies have enacted regulations with which all laboratories under their jurisdiction must comply. Organization, methods of reporting, quality control, and personnel requirements are no longer matters of personal choice. It would be impractical to attempt a detailed account of specific standards imposed by different regulating bodies. A brief summary of CLIA '88 Regulations follows this section. The suggestions for the organization of a cytology laboratory, discussed below, are general guidelines. Each laboratory must be aware of federal and local regulations with which it must comply.

Figure 44-20 Diagram suggesting a method of marking slides. The actual marking takes place under direct vision with a low-power scanning lens. In this diagram the dot is placed beneath the cells, as originally suggested by Papanicolaou. However, any other location of marking dots is acceptable, provided that it is constant and observed by all members of the same laboratory.

Screening of cytology material should be performed by well-trained and certified cytotechnologists. See CLIA '88 493.1467-1485) for specific requirements.

The duties of the cytotechnologists include cytopreparation or supervision of it; screening and marking of material; formulation of a preliminary diagnosis; and formulation of a final diagnosis in certain well-defined circumstances, such as the screening of an asymptomatic population.

1. The organization of a well-run, large laboratory of cytology is based on a system of checks and cross-checks to minimize errors (Fig 44-21). This system is based on identification of two major classes of material, one from symptomatic patients and the other from surveys of well population. Symptomatic patients include:
 - a. All patients from whom nongynecologic material is collected. Exceptions are special projects, such as screening for early lung cancer in asymptomatic patients, or rapid screening of all urine samples submitted for routine analysis.
 - b. Patients from whom gynecologic smears are obtained and who have a history of abnormal uterine bleeding, prior abnormal smears, cancer or precancerous states, or radiation therapy.

The diagram shown in Figure 44-21 offers a number of options in the handling of material. The first option (*solid lines*) suggests that all cases requiring review by a pathologist should be funneled through a senior or chief cytotechnologist. This system deprives the less experienced cytotechnologists of contact with the pathologist. The second option (*broken lines*) provides for a review of material by a senior cytotechnologist prior to presentation of the cases by the original screener to the pathologist. The third option (*dotted lines*) offers all cytotechnologists the opportunity to present cases directly to the pathologist. Regardless of the system adopted, channels of consultation at all levels of performance should remain open. It is particularly important for cytotechnologists at all levels of experience to be present when important diagnostic conclusions are reached on material screened by them. Open discussion of problem cases should be encouraged.

P.1628

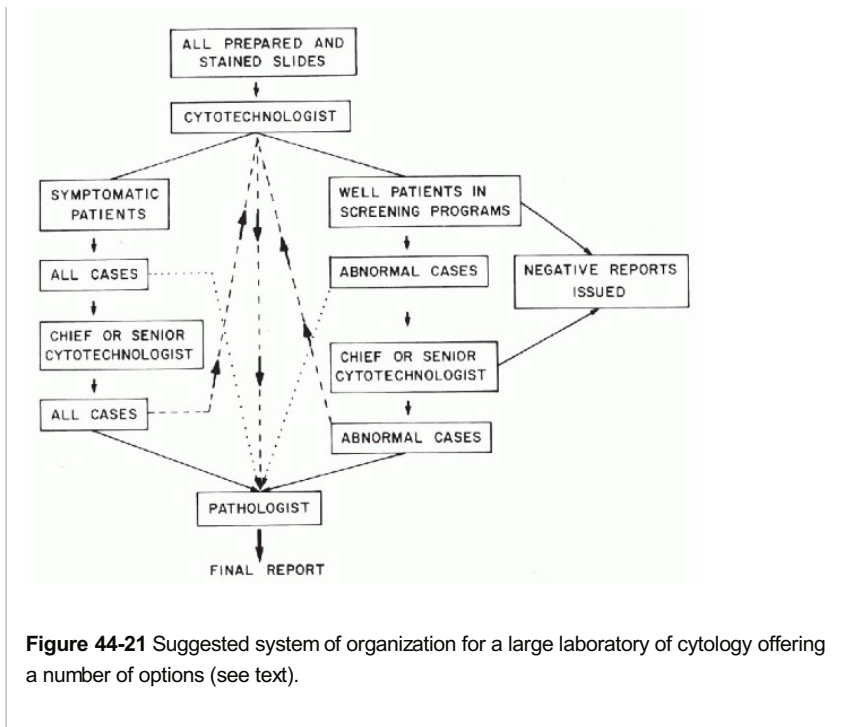

Figure 44-21 Suggested system of organization for a large laboratory of cytology offering a number of options (see text).

Quality Control

Quality control regulations vary depending on the agency or association responsible for accrediting a laboratory. Each laboratory director must be aware of and strictly adhere to local and federal regulations. We recommend that a quality control program include the following:

1. Correlate cytologic diagnoses with surgical, autopsy, and clinical findings on all patients.
2. Rescreen those cases in which the cytology and histology or clinical history do not correlate.
3. At the time of screening, review records of prior histologic and cytologic examinations for each patient.
4. Maintain a computerized cross-file or record-keeping system to allow data retrieval for statistical evaluation, such as percentage of positives.
5. Prepare annual statistical correlation reports.
6. Retain reports and slides in a readily accessible area for at least 3 years and keep cases exhibiting major abnormalities on file as long as the patient is alive, but not less than 5 years.
7. Set up internal performance evaluation programs to demonstrate the competency and accuracy of technical personnel.
8. Encourage participation of cytotechnologists in continuing education programs, both internal and external.
9. In our experience, the most important aspect of quality control is the constant review and correlation of cytologic findings with surgical and autopsy material. Particularly valuable is rescreening of previous material in patients who subsequently develop important abnormalities. For example, prior "negative" smears in patients with neoplastic lesions of the uterine cervix often will reveal missed evidence of disease. To this effect, a constant review of records is mandatory. *A computerized recording system combining cytologic and tissue diagnoses is of great assistance in such efforts.* A satisfactory internal quality control system is difficult to devise. This may, in part, be accomplished by rescreening a certain percentage of negative smears (e.g., 10%, as now required by the Centers for Disease Control) or by inserting material of known diagnostic values into the routine flow and checking the performance of cytotechnologists and pathologists against this standard. The latter system requires destaining, restaining, and renumbering of known cases, a rather formidable procedure.

Reporting of Cytologic Material

The report must include:

1. Name of patient and the laboratory accession number
2. Name of individual or facility to which the report is addressed

3. Name and address of the laboratory

P.1629

The following dates:

4. Sample collection
5. Sample received in the laboratory
6. Report issued
7. Cytologic diagnosis
8. Identification of cytopathologist and cytotechnologist responsible for the report.

Comment

Throughout this volume, it has been pointed out that an accurate cytologic diagnosis of disease is both possible and desirable; therefore, the reports should be expressed in simple language that can be readily understood by the clinician. At one time, Papanicolaou's classification of smears performed a very useful role. However, it was abandoned in this laboratory many years ago in favor of a nomenclature in keeping with the principle of surgical pathology. Thus, the presence of cancer is always reported and, at all times, an effort is made to determine—whenever possible—the histologic type, origin, and, occasionally, probable anatomic location of the tumor. In the absence of cancer, a simple diagnosis of “negative for malignant cells” is sufficient. If there is evidence of a noncancerous disease, this fact is also noted. The Bethesda reporting system for cervicovaginal material is summarized in Chapter 11.

No matter how skillful the pathologist may be, in a certain number of cases it will not be possible to make a definite diagnosis on the strength of the cytologic evidence available. This situation may be due to insufficient sampling of a lesion, to the unfavorable anatomic location of the lesion, or to the nature of a lesion that may be difficult to classify, even on the strength of very ample cytologic or histologic material. In such situations, a descriptive diagnosis of the findings is, in our experience, more satisfying than any classification and is usually acceptable to the clinician as well. Such descriptive diagnoses should not become the repositories of ignorance but may well express the uncertainty of the observer. The diagnosis of “suspicious” should be made only if a lesion has a definite neoplastic slant, although more evidence is needed for a definitive diagnosis. In such instances, it is wise to state, whenever possible, what type of lesion is anticipated. If the evidence is too scanty, even for the diagnosis of “suspicious,” it is best to withhold any opinion and simply ask for more material, never failing to mention the reason for the request.

CLIA 1988 REGULATIONS PERTAINING TO CYTOLOGY

The Clinical Laboratory Improvement Act passed by the United States Congress in 1988 (CLIA '88) was the response to the 1987 Bogdanicz report in the *Wall Street Journal* on women dying of cervical cancer because of cytologic screening errors. As a consequence, the practice of cervicovaginal cytology has become the most regulated field of laboratory medicine.

The following is a brief summary of some of the pertinent regulations affecting the cytopathology laboratories. It is by no means intended to be used as an all inclusive guideline. Original rules and regulations should be consulted when developing laboratory standards.

Specimen Acceptance and Adequacy

Each laboratory should have written criteria for rejecting specimens [CLIA '88 493.1200(b)(1)].

Test Requisition

The requisition must include [CLIA '88 493.1105(a-f)].

- Patient name (and/or unique identifier)
- Requesting physician's name and address
- Date of specimen collection
- Specimen source
- Pertinent clinical information
- For gynecologic smears the date of the last menstrual period, age or date of birth and pertinent history of prior abnormal reports, treatment, or biopsy

Test Records

Test records must include the following and be retained for at least 2 years [CLIA '88

493.1107(a-d)]:

- Patient name (and/or unique identifier)
- Date and time of specimen receipt in the laboratory
- Condition and disposition of unacceptable specimens
- Identity of personnel performing the test

Specimen Preparation and Staining

- For gynecologic specimens, a Papanicolaou (or modified) stain must be used [CLIA '88 493.1257(a)(1)].
- Measures must be in place to prevent cross-contamination [CLIA '88 493.1257(a)(2)].
- Nongynecologic specimens with a high potential for cross-contamination must be stained separately and stains filtered or changed following staining [CLIA '88 493.1257(a)(3)].

Screening and Reporting

All abnormal gynecologic smears interpreted as abnormal, which includes reactive or reparative changes, and all nongynecologic material, must be reviewed by the technical supervisor, in practice, a qualified cytopathologist [CLIA '88 493.1257(c)(1-2)].

The cytology report must:

- Contain a narrative descriptive nomenclature for all results [CLIA '88 493.1257(e)(2)]
- Clearly distinguish specimens or smears that are unsatisfactory [CLIA '88 493.1109(c)]
- The name and address of the laboratory [CLIA '88 493.1257(e)(1)]

P.1630

Corrected reports must indicate the basis for correction [CLIA '88 493.1257(e)(3)].

Cytotechnologist Performance

Individuals who screen cytological material may examine no more than 100 slides per day (24-hour period in no less than 8 hours) [CLIA '88 493.1257(b)(1-3)(ii)]. The limit has been increased to 200 slides for material from automated devices that deposit cells in small circles.

Records of the total number of slides screened by each individual each 24 hours, irrespective of the site and the number of hours examining slides, must be maintained [CLIA '88 493.1257(b)(3)].

The performance of each cytotechnologist in comparison to overall laboratory performance must be evaluated. Discrepancies and corrective action, if appropriate, must be documented [CLIA '88 493.1257(d)(5)].

Quality Assurance

Ten percent of all negative gynecologic smears must be selected at random and from high risk patients, to be rescreened prior to reporting of the results. Records of the initial review and rescreening must be kept [CLIA '88 493.1257(d)(1) (i-iii)].

The laboratory must compare clinical information and cytology report. Premalignant cytology reports should be compared to histopathology reports when available [CLIA '88 493.1257(d)(2)].

For each new high-grade or above lesions detected by cytology or histology, **a 5-year retrospective review of negative smears must be performed**. If significant discrepancies are found that would affect patient care, the laboratory must notify the patient's physician and issue an amended report [CLIA '88 493.1257(d)(3)]. Other aspects of quality control in cervicovaginal cytology are discussed in Chapter 11.

ACKNOWLEDGMENT

We gratefully acknowledge the assistance of Gina Powell, H.T. (ASCP), former Chief Histotechnologist at Montefiore Medical Center, for her guidance and advice on the section Other Stains Useful in Diagnostic Cytology.

Immunocytochemistry and Molecular Biology in Cytological Diagnosis

Ronald A. DeLellis

Rana S. Hoda

As we develop methods for extrapolating the secrets previously locked within the individual cells, it becomes evident that the cells were talking all along; we just did not know how to listen.

—(Abati et al, 1998)

The past several decades have witnessed the development of a remarkable array of methodological advances in the biomedical sciences. One of the most successful of these approaches has been immunocytochemistry. Methodologies employing antibodies as specific probes for the visualization of cell and tissue bound antigens have literally revolutionized the practice of pathology (Taylor, 1978; DeLellis et al, 1979; Taylor, 1994; Wick et al, 2001). The application of these methods has permitted the extension and expansion of morphology by means of increasingly more sensitive and specific markers that can be visualized in single cells and in tissue sections. Experience gathered over the past three

P.1636

decades has indicated that the success of any immunohistochemical procedure depends on multiple factors, such as the antigen preservation, the specificity and avidity of the primary antibody and the sensitivity of the detection system. These factors are interrelated; reliable and reproducible results can be achieved only when each variable is optimized.

Immunocytochemistry on cytologic material has great potential utility as recognized by Nadji and others in the early to mid-1980s; however, problems with scanty cell samples, high levels of nonspecific background staining and falsepositive and false-negative reactions have limited the widespread application of this technique (Nadji, 1980; Chess and Hadju, 1986). Improved cytological collection methods, together with advances in immunocytochemical technology, including the development of new monoclonal antibodies and more sensitive detection methods, have led to greater degrees of sensitivity and specificity in cytological preparations (Ramaekers et al, 1988; Flens et al, 1990; Domagala and Osborn, 1992; Dabbs et al, 1995; Abati et al, 1998; Bedrossian, 1998; Dabbs and Wang, 1998; Fetsch and Abati, 1998). Shield et al (1996) analyzed the utility of immunocytochemical methods in cytology over a 20-month period and demonstrated that this approach was helpful in approximately 75% of cases. In body fluids, staining was performed most commonly for the distinction of mesothelial cells from metastatic malignancies. Immunocytochemistry was helpful in 82% of these cases with the preliminary diagnosis confirmed in 64%, refined in 8% and revised in 10%. In fine needle aspiration (FNA) samples, staining was helpful in 69% of cases, resulting in refinement of the diagnosis in 55% and confirming the preliminary diagnosis in 14%. In one case, these studies led to a revision of the original interpretation. In cytology, the practical utility of immunocytochemistry includes characterization of poorly differentiated neoplasms, differentiation of primary from metastatic tumors, determination of the sites of origin of metastatic lesions and prognostic assessments.

The purpose of this chapter is to provide an **overview of immunocytochemical methods**, their applications and limitations in different types of cytological preparations and their contributions to the understanding of neoplastic disorders. In addition, this chapter **highlights molecular techniques** that are of value in the analysis of cytological samples. For additional details including use of sophisticated techniques, such as linker and polymer-based staining, the reader is referred to the textbook by Dabbs (2002).*

PREPARATORY METHODS AND ANTIGEN PRESERVATION

Numerous preparatory techniques have been utilized for the immunochemical evaluation of cytological preparations (Table 45-1) (Sherman et al, 1994; Hunt et al, 1998; Mitteldorf et al, 1999). When sufficient material is available, formalin-fixed paraffin miniblocks and cell blocks

offer a number of advantages since fixation and subsequent processing are essentially identical to those used for tissue sections (Domagala et al, 1990; Bellotti et al, 1997; Fowler et al, 1998). Moreover, antibody panels and multiple positive and negative controls can be applied to the same material. When the amount of cellular material is limited, other preparations including direct smears (unstained or previously stained), cytocentrifuge preparations, cells collected on filters or in liquid fixatives and cell transfers can be used (Table 45-1) (Sherman et al, 1994; Abendroth and Dabbs, 1995; Leung and Bedard, 1996; Gill, 1998).

Fixation

The **choice of appropriate fixative** plays a critical role for the optimal preservation of the antigen of interest and numerous standard and novel fixatives have been used for this purpose (Okuyama et al, 1996). **Prompt fixation** is necessary to minimize diffusion and extraction of soluble antigens and to preserve morphological integrity. **Delays in fixation** may lead to a loss or significant reduction of immunoreactivity due to diffusion of antigens from their intracellular sites and autolytic processes. **Autolysis** also results in nonspecific binding of antibodies to unrelated antigenic determinants. Despite this fact, a variety of antigens **can be localized, even in necrotic samples** of both histological and cytological preparations, **provided that appropriate controls are used** (Judkins et al, 1998; Marzec et al, 2001). **Buffered neutral formalin (4% formaldehyde)** is compatible with the localization of many antigens, both in histological and cytological samples. The popularity of this fixative is based on many factors, including its low cost, ease of preparation and its preservation of morphological detail (Werner et al, 2000). The basis of formalin fixation is the formation of hydroxyl-methylene type linkages between protein end groups which increase with the length of fixation time. An additional mechanism is the formation of coordinate bonds for calcium ions (Werner et al, 2000). **Prolonged fixation in formalin**, however, often **leads to reduced immunoreactivity** of many antigens, primarily because of the steric hindrance resulting from the formation of extensive crosslinkages. Crosslinks may be formed between two parts of the antigen resulting in masking of the epitope or between two or more different molecules. Such linkages may also directly affect the epitope itself (Werner et al, 2000). In the past, several approaches, including washing of sections with buffer or treatment with proteolytic enzymes, were used in restoring the reactivity of many epitopes. More recently, **antigen retrieval** methods based on the use of **microwave heating** of sections have permitted the localization of most antigens of interest to the pathologist as discussed in the next section.

In cell blocks prepared from previously alcohol-fixed spun sediment, **fixation in formalin of less than 24 hours**

P.1637

may result in a mixture of formalin fixation and ethanol fixation, the latter resulting from tissue processing in graded ethanols. Brief formalin fixation will result in cross-link formation only at the periphery of the block while the center will be fixed in ethanol. As a result, sections prepared from such blocks may show **variable staining** that is more or less intense staining at the center or periphery, depending on the reactivity of the antibody and the retrieval procedure employed (Werner et al, 2000).

TABLE 45-1 IMMUNOCYTOCHEMISTRY USING DIFFERENT TYPES OF CYTOLOGICAL PREPARATIONS			
Preparation	Fixative	Advantages	Disadvantages
Cell blocks (occasionally small tissue fragments retrieved from aspirated material)	Formalin fixation is usual; however, other fixatives may be used depending on nature of antigen	- Staining conditions virtually identical to standard histologic preparations - Good cellular morphology and nuclear detail - Serial sections may be prepared for use with antibody panels - Standardization of retrieval methodology	- Requires relatively large amount of material - Cannot be used with highly labile antigens - Processing time is longer than with direct smears - Effects of prolonged storage are unknown

Direct smears	Alcohol or formalin fixation	<ul style="list-style-type: none"> - May be the only material available for analysis - Cellular areas can be subdivided or cells can be peeled off for multiple antibody tests - Previously stained slides can be used with or without prior decolorization 	<ul style="list-style-type: none"> - Limited material may compromise use of antibody panels and appropriate controls - Cell loss may occur during staining - Three dimensional cell groups may "trap" antibodies leading to nonspecific staining - Mechanical smearing process may lead to disruption of cells and leakage of antigens - Requires large quantity of antibodies and other reagents - Potential for high background staining due to blood and necrotic material
Cytocentrifuge preparations	Alcohol or formalin fixation	<ul style="list-style-type: none"> - Lack of background staining - Ease of interpretation since cells are concentrated in a small area - Multiple slides can be prepared - Relatively small amounts of antibodies or other reagents are used 	<ul style="list-style-type: none"> - Significant amount of cellular material may be lost during cytocentrifugation process - Lack of reproducibility if processing is not well controlled
Filters	Alcohol or formalin fixation	<ul style="list-style-type: none"> - Provides optimal recovery of cells 	<ul style="list-style-type: none"> - High non-specific background staining
Thin Prep (Cytoc Corp., Marlborough, MA) SurePath (TriPathology Imaging, Burlington, NC)	Proprietary fixatives	<ul style="list-style-type: none"> - High cell yield in initial preparations - Clean background and absence of air-drying effect - Multiple slides and cell blocks from residual material - Relatively small amount of antibody required 	<ul style="list-style-type: none"> - Decreasing cell yield with sequential preparations - High cost - Certain markers (e.g., lymphoid markers) may be difficult to demonstrate

- Single
preparations can
be subdivided

In addition to formalin, other fixatives have been employed for the demonstration of cell and tissue bound antigens, including the mercury containing fixatives such as Zenker's and B5 (formol sublimate), picric acid containing fixatives (Bouin's and Zamboni's) and alcohol-based fixatives such as Carnoy's fluid (alcohol, chloroform, acetic acid) (see Chap. 44). Additionally, ethanol, methanol and acetone have been used as primary fixatives for a variety of immunochemical applications. Alcohol and acetone are

P.1638

precipitating or coagulating fixatives rather than cross-linking reagents; accordingly, retrieval procedures are not generally useful in restoring reactivity following fixation with these reagents. However, for some antigens a retrieval step may help in such preparations provided that the cells have been collected on adhesive slides.

It should be noted that fixatives can markedly alter the reactivity of antigens to antibodies since exposure patterns of epitopes can differ. As noted by Willingham et al (1999), most of the epitopes (the parts of antigens reacting with antibodies; for full explanation, see below) that are detectable by monoclonal antibodies are conditional in the sense that they are reactive only under certain conditions. For example, Josephsen et al (1999) have demonstrated that a monoclonal antibody directed against vimentin reacts with a novel epitope on an unrelated protein (amelogenin), but this phenomenon occurred only after fixation in 1% glutaraldehyde or 4% paraformaldehyde plus 0.1% glutaraldehyde but not with 2.5% glutaraldehyde. Blocking experiments demonstrated that the amelogenin antibody competed with the vimentin antibody.

The ideal fixative for immunocytochemistry of cytological preparations should be convenient to use and should provide both optimal antigen preservation and cellular morphology. Suthipintawong et al (1996, 1997) examined the effects of a large number of fixatives including acetone, acetone/methanol, acetone formalin, glutaraldehyde, ethanol, methanol and formol saline on antigen preservation. They concluded that **fixation of air-dried smears** in 0.1% formol saline (normal saline 1,000 ml and 40% formalin 2.5 ml) overnight at 27°C followed by 10 minutes fixation in 100% ethanol produced the most consistent results. Air drying is an important step since it minimizes the cell loss that inevitably occurs when fresh smears are immersed directly into fixative. As noted by Leong et al (1999), postfixation in ethanol is not essential for the preservation of immunoreactivity but improves the cytomorphological features. Formol saline produces complete hemolysis of background erythrocytes and removal of background proteinaceous fluid. Moreover, immunoreactivity can be further enhanced by **microwave-induced epitope retrieval** following formalin fixation. For air dried smears, adhesive-coated glass slides were not required. The smears could be kept at room temperature for at least 7 days and at - 70°C for 5 weeks without loss of immunoreactivity as air dried smears or after fixation in formal saline.

Abati et al (1998) have recommended short term storage of unfixed air dried cytological preparations at 4°C and long term storage at - 20°C in desiccant. Following removal of the slides from the refrigerator or freezer, it is important to allow the containers to equilibrate to room temperature prior to opening. They further recommend that the choice of fixative should be tailored to the particular antigen under study. For **hematopoietic markers**, they recommend 10 minutes fixation in acetone while a 1:1 mixture of methanol and absolute ethanol is used for **nonhematopoietic markers**. They recommend fixation in 3.7% buffered formalin for 15 minutes for those markers which have a **nuclear localization** (e.g., steroid receptors, p53). Freeze drying and freeze substitution methods have also been used for preservation of antigenicity in cytological materials (Takahashi et al, 1996).

Antigen Retrieval Methods

Suboptimal preservation of antigens is a major factor leading to lack of staining consistency in immunohistochemistry and, even more so, in immunocytochemistry.

The effects of formalin fixation can be reversed in part by prolonged washing of cells and tissues in water or buffer. **Proteolytic enzyme digestion** of formalin fixed samples has proven to be an invaluable approach for the unmasking of some formalin sensitive epitopes. However, some antigens are highly susceptible to the effect of proteolysis and may be completely destroyed even after relatively brief periods of enzyme treatment. Proteolytic enzyme induced unmasking most likely results from breakage of formaldehyde induced cross links in the antigen itself, with exposure of cryptic epitopes or hydrolysis of adjacent macromolecular complexes that may have covered or masked the epitopes of interest. Optimization of the time of proteolysis appears to be more crucial to the success of this approach than the particular enzyme used. Generally, tissues fixed for prolonged time periods require the most extended

periods of enzyme digestion.

A major advance in the retrieval of formalin sensitive epitopes involves the use of **moist microwave heating of tissue samples**. Pioneered by Shi et al (1991), antigen retrieval using microwave heating of sections immersed in 1% zinc sulfate or saturated lead thiocyanate resulted in significant increases in immunostaining with a high proportion of tested monoclonal antibodies. The precise mechanism by which microwave heating restores immunoreactivity, however, remains unknown. One possibility is that heating can lead to disruption of formalin induced bonds between proteins and calcium ions (Mogan et al, 1994). The most commonly used method utilizes microwave heating in 0.01 mol/L citrate buffer at pH 6.0. Other heating approaches include the use of pressure cookers and rice steamers. This method has also been applied successfully to cytological samples (Reynolds et al, 1994; Schmitt et al, 1995).

Since the types and lengths of fixation may differ widely a “**test battery**” approach has been proposed (Shi et al, 1996; Taylor and Shi, 2001). This approach is based on the heating conditions and the pH of the retrieval solution. According to Shi et al (1996), a maximal retrieval level that shows the strongest staining intensity can be established by using this test battery. The use of an optimal retrieval protocol permits comparable staining results for a variety of archival tissues that have been fixed in formalin for widely different time periods. **The heat induced antigen retrieval methods also have potential pitfalls**. Since most monoclonal antibodies react with epitopes containing three to eight amino acids, retrieval methods could potentially expose unwanted epitopes of identical sequence in other antigens. This could lead to unexpected cross reactions and the problem of **false positive reactions** as discussed previously. Heat induced methods have also been used for the retrieval

P.1639

of DNA and RNA from archival samples. Heat induced antigen retrieval may also result in enhanced reactivity of **endogenous biotin**. This is particularly problematic in mitochondria-rich cells. When using an avidin biotin-based detection system, therefore, it is critical that **endogenous biotin be blocked with avidin** prior to staining (Rodriquez-Soto et al, 1997) or that a non-avidin—biotin system be used.

ANTIBODIES AND IMMUNOCYTOCHEMICAL METHODS

Antibodies are immunoglobulin molecules that are produced by B cells. They consist of a **pair of light chains** (kappa or lambda) and a **pair of heavy chains** (gamma, alpha, mu, delta, or epsilon) that are joined together by disulfide bonds (Listrom and Fenoglio-Preiser, 1992; Abbas et al, 2000). IgG has two antigen binding sites, each of which is able to bind with one molecule of the antigen. The antigen binding sites are located in the Fab region of the molecule and are formed by the N-terminal ends of the light and heavy chain pairs. Antigen binding occurs in that region of the Fab fragment that contains the variable domains of both the heavy V_H and light V_L chain gene sequences. Specificity is determined by the precise amino sequences of the variable domains. The Fc portion of the antibody molecule contains only heavy chains and accordingly does not bind to the antigen. However, the Fc portion of the molecule can react with receptors on the surfaces of many cells and can lead to non-specific binding of antibodies to cells. Complement binding sites are also present on the Fc portion of the immunoglobulin molecule and are another potential source of non-specific staining in immunohistochemical formats.

An antibody binds only to a specific portion of an antigen which is called a determinant or epitope. With phospholipids or complex carbohydrates, the antigenic determinants are a function of the covalent structure of the macromolecule. Noncovalent folding of protein macromolecules also contributes significantly to the formation of antigenic determinants.

Epitopes are generally small and consist typically of three to eight amino acids. Those epitopes formed by adjacent amino acids in the molecule are termed **linear or continuous determinants**. If continuous epitopes are present on the surface of the native protein antigen, they will be able to react with the corresponding antibody. More often, continuous epitopes may be inaccessible to the antibody in their native conformation and will become reactive only when the antigen is denatured. **Discontinuous epitopes** are formed by amino acid sequences from separated portions of the molecule that are juxtaposed only in their native folded state. Such epitopes are typically lost upon denaturation of the molecule. This phenomenon explains, at least in part, **discrepancies between the results of antibody assays using immunohisto- or cytochemical and Western analyses** (Willingham, 1999).

Although the two binding sites of an immunoglobulin molecule could bind to two separate epitopes on the same or separate molecules of the antigen, probably only one site is bound to antigens in tissues. An antigen with several determinants could bind several molecules of antibody or could bind several antibodies of differing specificities directed against two or more different determinants present in the same antigen. Because of the relatively small number of amino acids in an epitopic sequence, **cross reactivities of antibodies may occur in**

unrelated proteins and are a continual source of concern in immunochemical assays. A conformational change in an epitope, resulting from changes in pH, type and duration of fixation, temperatures of processing and exposure to solvents may, therefore, have a profound impact on the reactivity of the antibody with the epitope.

Although many early immunochemical studies were performed with polyclonal antisera, more recent studies have utilized monoclonal antibodies (Taylor and Cote, 1994). Polyclonal antisera are prepared by injecting the immunogen of interest into an animal with the subsequent stimulation of multiple B-cell clones, each of which produces a single antibody which is specific for the inducing epitope. **Polyclonal antisera, therefore, contain multiple different antibodies with varying specificities and affinities.** Repeated immunizations with the same antigen increase the selection process and usually lead to the production of antisera containing high affinity antibodies.

Polyclonal antisera have both advantages and disadvantages in immunochemical formats. Advantages include the presence of a complex mixture of high- and lowaffinity antibodies to different epitopes with a resultant increased probability of antigen antibody interactions. As a result, more antibody may react with an antigen molecule. In order to produce a useable reagent, however, **antisera must be absorbed with unwanted antigens** and should be affinity purified with pure antigen. Since pre-existing antibodies may also be present in antisera and may lead to misleading patterns of reactivity, preimmune sera are invaluable controls to eliminate this possibility.

In contrast, **monoclonal antibodies are restricted in their specificity** to a single epitope (Taylor and Cote, 1994). Monoclonal antibodies are prepared by **fusing lymphocytes from immunized mice with a murine myeloma cell line**, as first described by Köhler and Milstein in 1975. The resultant **hybridoma** producing the antibody of interest is separated from the other clones and is propagated in vivo or in vitro. This procedure results in an unlimited supply of antibody of consistent characteristics in contrast to the batch variations of polyclonal antisera. Several problems can be encountered with monoclonal antibodies. Generally, since monoclonal antibodies recognize a relatively short amino acid sequence, the potential for unexpected crossreactivities exists. Moreover, a higher level of sensitivity is needed when antigens are present in low concentrations. In order to circumvent this problem, **mixtures of monoclonal antibodies (cocktails)** to different epitopes on the antigen of interest may be used. Selective masking of epitopes as a result of fixation and processing may also lead to significant loss of binding with monoclonal antibodies.

P.1640

Immunofluorescence

Immunofluorescence techniques were first developed in the 1940s; however, they did not gain widespread acceptance until the following decade when they became invaluable tools in the developing field of experimental immunology (Coons et al, 1942). Since that time, immunofluorescence methods have been used extensively as diagnostic tools, particularly in the **classification of renal diseases** and in other immunologically mediated disease process. The technique is based on labeling of antibodies with a fluorescent substance. Fluorescence microscopy will reveal the site of the antigenantibody product in cells or tissues. Subsequently, these methods were utilized for the **demonstration of a variety of cell products** including immunoglobulins, hormones, enzymes and onco-developmental antigens. Principal drawbacks to the widespread adoption of immunofluorescencebased methodologies in surgical pathology included a relatively **low sensitivity** with the resultant necessity for **fresh frozen tissues**, lack of sufficient morphological detail, impermanency of stains and the need for specialized microscopy.

Enzyme Conjugates

Immunoenzymatic techniques employing **antibodies conjugated with enzymes** (horseradish peroxidase, glucose oxidase, alkaline phosphate) were introduced in the mid 1960s as an alternative to immunofluorescence methods. The most frequently used procedures employed direct or indirect staining sequences with **horseradish peroxidase** in place of fluorescein isothiocyanate (Nakane and Pierce, 1996). In the direct method, horseradish peroxidase was conjugated to the primary antibody. The indirect method employed a two stage procedure involving application of the primary unconjugated antibody followed by a peroxidase conjugated antibody derived from a second species and directed against the globulin fraction of the primary antibody. Sites of binding were then visualized by reaction with hydrogen peroxide (the substrate) and a chromogen to produce a color reaction product. Although this approach did not provide greater sensitivity than direct or indirect immunofluorescence, its major advantage was that the results could **be studied in a light microscope**, thereby eliminating the need for a fluorescence microscope. Moreover, the enzyme conjugate methods could be used for correlative ultrastructural studies because of the electron density of the reaction product and

labelling with colloidal gold.

The chromogen most commonly employed in peroxidase procedures is **3-3' diaminobenzidine tetrahydrochloride**, which produces an insoluble reaction product upon oxidation (Nakane and Pierce, 1996). The resultant slides are then counterstained, dehydrated and mounted with excellent preservation of morphological detail. **Alternative chromogens include 4-chloro-1-naphthol and 3-amino-9-ethylcarbazole**, which yield blue and red reaction products, respectively (Taylor and Cote, 1994).

Unlabeled Antibody Enzyme Procedures

The immunoglobulin enzyme bridge and peroxidase antiperoxidase methods represented major advances in the development and widespread application of immunohistochemistry by pathologists. Although the immunoglobulin enzyme bridge method now has relatively few applications, the **peroxidase-antiperoxidase technique continues to be used in some laboratories** (Sternberger et al, 1970). The latter method involves the sequential application of a **primary antiserum**, a bridge or **secondary antiserum** with specificity directed toward the globulin fraction of the primary antiserum and a **soluble peroxidase-antiperoxidase complex** prepared in the same species as the primary antiserum. The bridge antibody is added in molecular excess so that binding of one of its antigen combining sites will interact with the primary antiserum and the second will be free to combine with the peroxidase antiperoxidase complex. The peroxidase-antiperoxidase method possesses considerably higher sensitivity than the conjugate methods. The high sensitivity is due to virtual absence of background staining with a resultant high signal to noise ratio. The development of this method basically permitted the use of formalin-fixed, paraffin-embedded tissues in place of the frozen samples generally required for immunofluorescence and enzyme conjugate procedures. Although the peroxidase antiperoxidase method was developed initially for polyclonal antisera, this approach can also be used for monoclonal antibodies since a murine peroxidase antiperoxidase complex is available.

Avidin-Biotin Procedures

Avidin is 68KD glycoprotein which has **four binding sites** for the low molecular weight vitamin, **biotin**. The interaction of biotin with avidin has an association constant that is several million times greater than antigen-antibody binding. In the method developed by Guesdon et al (1979), which was referred to as the bridged biotin-avidin technique, sections were incubated sequentially with biotin labeled primary antibody, avidin, and biotin labeled horseradish peroxidase or other enzymes. This approach has been largely supplanted by the avidin-biotin peroxidase (ABC) method and the streptavidin biotin procedure. In the ABC procedure, sections are sequentially incubated with the primary antibody, a biotinylated secondary (bridge) antibody and preformed complexes of avidin and biotin horseradish peroxidase (Hsu et al, 1981; Hsu and Raine, 1984). The intensity of staining with this procedure is due to the formation of a lattice-like structure containing multiple peroxidase molecules.

In the **streptavidin-biotin peroxidase procedure**, **avidin is replaced with streptavidin** which is conjugated to the enzyme molecule (labeled streptavidin biotin procedure). Similar to avidin, streptavidin also possesses a high affinity for biotin; however, because of the absence of carbohydrates, non-specific binding is less of a problem than with avidin. Non-specific binding due to electrostatic interactions is lessened substantially because of streptavidin's lower isoelectric point. These features generally result in high signal to noise ratios.

P.1641

Polymer-Based Methods

A variety of methods employing natural or synthetic polymer carriers to increase the number of enzymes or ligands that are coupled to linker antibodies have been developed (van der Loos et al, 1996; Sabbatini et al, 1998; Shi et al, 1999; Kammerer et al, 2001). Polymeric carriers that have been used include dextran, polypeptides, dendrimers and DNA branches. In the **direct enhanced polymer one-step staining (EPOS) system**, primary antibodies and horseradish peroxidase are coupled to a divinyl sulfone activated dextran polymer. An indirect polymer method has also been developed by Dako Laboratories (En Vision).^{*} With this procedure, tissues are first incubated with the primary antibody and are then incubated with a polymeric conjugate consisting of a large number of peroxidase and secondary antibody molecules bound to an activated dextran backbone. The polymeric conjugates hold up to 100 enzyme molecules and up to 20 antibody molecules per backbone (Sabbatini et al, 1998). The indirect system provides considerably greater flexibility than the direct method since the primary antibody can be varied. The use of this polymer based approach circumvents false positive staining due to endogenous biotin (Vyberg and Nielsen, 1998). Comparative studies indicate that the polymer-based **En Vision method** possesses a sensitivity which exceeds that of the ABC or labeled streptavidin methods (Sabbatini et al, 1998). This method has been adapted for use with frozen sections (Kammerer et al, 2001) and is capable of detecting a broad range of antigens in less

than 13 minutes.

Some studies have suggested that the **sensitivity of this method** for the detection of certain antigens **may be decreased** because of the spatial hindrance afforded by the high molecular weight of the dextran carrier. In order to circumvent this problem, Shi et al (1999) have utilized a more compact enzyme linker antibody conjugate with a high number of enzyme molecules attached to each linker antibody with minimal increase in molecular size (**Power Vision System**). The Power Vision reagent is derived from small, multifunctional, polymerizable linkers that are used to activate a mixture of enzymes and linker antibodies with polymerization occurring under controlled conditions (Shi et al, 1999). The result of this polymerization process is an enzyme linker antibody with a more compact molecular shape than other types of polymers, thereby allowing the attachment of multiple conjugates in close proximity to one another. This procedure also circumvents problems with endogenous biotin.

Protein A Methods

Protein A is a cell wall constituent of most *S. aureus* strains and consists of a **single polypeptide chain** with a molecular weight of 42,000. Protein A has a high affinity for the Fc portion of immunoglobulins, particularly of the IgG class. Although the interaction of protein A with immunoglobulins is non-immunological, the avidity of binding is comparable to that of antigen-antibody interactions. The two stage protein A immunoperoxidase method consists of the application of the primary antiserum followed by protein A conjugated with horseradish peroxidase (Notani et al, 1979). A three-step procedure utilizes protein A as a link between the primary antiserum and the peroxidase antiperoxidase complex. **Protein A has also been linked to colloidal gold particles** which can be visualized both by light and **transmission electron microscopy** (Roth and Heitz, 1989). Since colloidal gold particles of different defined diameters are now available, multiple antigens can be localized at the ultrastructural level with this approach.

Catalyzed Reporter Deposition (CARD) Method

The basis for the catalyzed reporter (CARD) method, also known as **the tyramide amplification technique (TAT)**, relies on the ability of horseradish peroxidase to catalyze the dimerization of biotinylated tyramine (tyramide), thereby permitting the deposition of a large number of avidin-biotin-peroxidase complexes or peroxidase-labeled streptavidin molecules. It has been suggested that the highly reactive phenol moiety of tyramide intermediates generated by the tyramide signal amplification process binds to amino acids in close proximity to the horseradish peroxidase molecule. Although this methodology was initially developed for the enhancement of enzyme-linked immunoabsorbent and Western blot assays, it has now been successfully adapted for immunochemistry, immunoelectron microscopy and in situ hybridization (Bobrow et al, 1989; von Wasielewski et al, 1997; Sanno et al, 2001). In this procedure, sections are incubated sequentially with the primary antibody, a biotinylated secondary antibody, the streptavidin biotin peroxidase complex, biotinylated **tyramine (amplification reagent)** and streptavidin peroxidase. von Wasielewski et al (1997) found a 5- to 50-fold (maximum 500) increase in sensitivity with the CARD method when compared with conventional immunochemical approaches with a wide range of antibodies. Additional studies, however, will be required before this approach is accepted as a standard diagnostic procedure.

Double Staining Techniques

Double immunoenzymatic techniques have been developed for the **localization of two antigens** in histological and cytological preparations (Taylor and Cote, 1994). In general, this procedure is performed by visualizing the distribution of the **first antibody** with one of the immunoperoxidase methods using diaminobenzidine as the chromogen. The **second antibody** is demonstrated by using a different chromogen (4-chloro-1-naphthol or amino ethylcarbazole). The preferred **chromogen combination** is diaminobenzidine and 4-chloro-1-naphthol, which produce the contrasting colors of brown and blue, respectively. Alternatively different enzymes and substrates (alkaline phosphatase or

P.1642

glucose oxidase) can be used in the antibody labeling systems (Lam et al, 1988; Gown, 1988).

CONTROLS

The use of appropriate **positive and negative controls** is essential for the interpretation of immunochemical stains (Table 45-2). This is particularly **critical for cytologic preparations** where conditions are significantly different from those in fixed and embedded tissues which are used most often as controls. **Positive controls** should contain the antigen of interest and should be processed in an identical fashion to the test case. For this purpose, it may be possible to establish a **bank of imprints or frozen cells** from normal and neoplastic tissues containing the antigen of interest **as well as cells expected to be negative for the antigen**.

There should also be sufficient cells in the test case to perform **negative controls with an irrelevant antiserum or monoclonal antibody**. If a **single slide** is available, **portions of the same slide may be used for the test and negative control** by circling areas of interest with a diamond pen or wax crayon or using **the cell transfer technique using liquid coverglass medium** (Sherman et al, 1994). Antibody specificity is best determined by immunoblot or immunoprecipitation methods (Burry, 2000). Absorption of the antibody with a protein does not determine that the antibody would have bound to the same protein in the tissue and may, therefore, not be an optimal control for antibody specificity. **Method specificity is best determined by a negative control** (irrelevant monoclonal antibody, preimmune serum) and a **positive control** with cells known to contain the protein of interest. The validation of ambiguous results should be assessed by using antibodies to different epitopes of the same molecule and by the use of antibodies to related markers (Seidal et al, 2001).

TABLE 45-2 FALSE-POSITIVE STAINING

Source of Problem	Solution
Endogenous enzyme activity	
Peroxidase	Pretreatment with methanol and hydrogen peroxide, sodium azide and hydrogen peroxide or cyclopropane hydrate.
Alkaline phosphatase	Enzyme activity is destroyed in routinely fixed and embedded tissue. If frozen sections or smears are used, endogenous enzyme activity can be blocked with levamisole.
Glucose oxidase	This enzyme is absent from vertebrate cells and is not problematic.
Hydrophobic/ionic interactions of antibodies	Pretreatment of preparations with an irrelevant antibody or normal serum.
Crossreactivity of secondary antibody with tissue components	Absorption of secondary antibody with purified IgG of species from which test tissue is obtained. Use of affinity purified antibody.
Avidin binding	
Electrostatic interactions	Use alkaline pH. This problem can be avoided with streptavidin.
Endogenous biotin*	Preincubation of preparations with avidin followed by biotin.
Free tissue aldehydes	Pretreatment with sodium borohydride, ammonium chloride, glycine or lysine.
Binding of Fc portion of antibody molecule	Use Fab fragments.
Crossreactivity of primary antiserum	Use affinity purified antibodies.
* Endogenous biotin activity is markedly enhanced following microwave induced antigen retrieval.	

Cell lines have also been utilized as controls (Kurtycz et al, 1997). This approach provides essentially unlimited supplies of cells that can be used as both positive and negative controls. With the development of increasing numbers of quantitative prognostic markers, the use of

appropriate controls has become a critical issue. Seidal et al (2001) have suggested an approach based on **the suspension of cells expressing known and independently measured quantities of the antigen** within the tissue cassette **together with the unknown specimen**. With this approach, both the

P.1643

specimen and control are subjected simultaneously to identical fixation, processing, retrieval, staining, and interpretation. This approach, however, does not circumvent other important preanalytic variables, such as antigen degradation during transport of fresh specimens or fixation time if the specimens are delivered to the laboratory in the fixed state.

REGULATORY ISSUES

Most antibodies employed by pathologists and cytopathologists are classified by the Food and Drug Administration (FDA) as Analytic Specific Reagents and **class I medical devices** which exempts them from premarket notification (Food and Drug Administration, 1998; Roche and Hsi, 2001). This ruling is based on the fact that most immunostains do not provide “stand-alone” results, but rather that the results are incorporated into a surgical pathology or cytopathology report as one component of the entire diagnostic evaluation. **Class II medical devices** refer to those immunostains (e.g., estrogen and progesterone receptors) which do not have routine morphological correlates but have substantial and widely accepted scientific validation. **Class III devices** include reagents that are not part of the surgical pathological or cytopathological diagnostic process and may result in an independent report (e.g., Hercep Test). Class III devices require premarket notification and FDA approval. **Surgical pathology and cytopathological reports should include a statement that indicates that the responsibility for assuring quality of the immunostains rests with the individual laboratory and not the manufacturer of the reagents.**

According to NCCLS (National Committee for Clinical Laboratory Standards) guidelines, the results of immunohistochemistry or cytochemistry should be incorporated into the final pathology report. When this is not possible, the immunochemical findings should be issued as an addendum. The report should include a description of the specimen, the type of fixative, the antibody (clone number and generic description). **The report should also include the results of all tests performed together with information on the reactivities of positive and negative controls and on the localization of staining (nuclear vs. cytoplasmic vs. plasma membrane).**

TABLE 45-3 INTERMEDIATE FILAMENTS

Intermediate Filament Type	Mol Wt	Distribution
Cytokeratins	44-68 kD	Epithelial cells
Vimentin	57 kD	Mesenchymal, epithelial and neural cells
Desmin	55 kD	Muscle cells
Glial fibrillary acidic protein	48-52 kD	Fibrous and protoplasmic astrocytes, some ependymal cells, cerebellar radial glia, Muller cells of the retina, developing oligodendrocytes, non-myelinated Schwann cells, some cells of pituitary, breast and adrenal
Neurofilaments	70-200 kD	Neuronal cells

EPITHELIAL MARKERS

Cytokeratins

The cytokeratins are members of the intermediate (10-nm) filament family of cytoskeletal

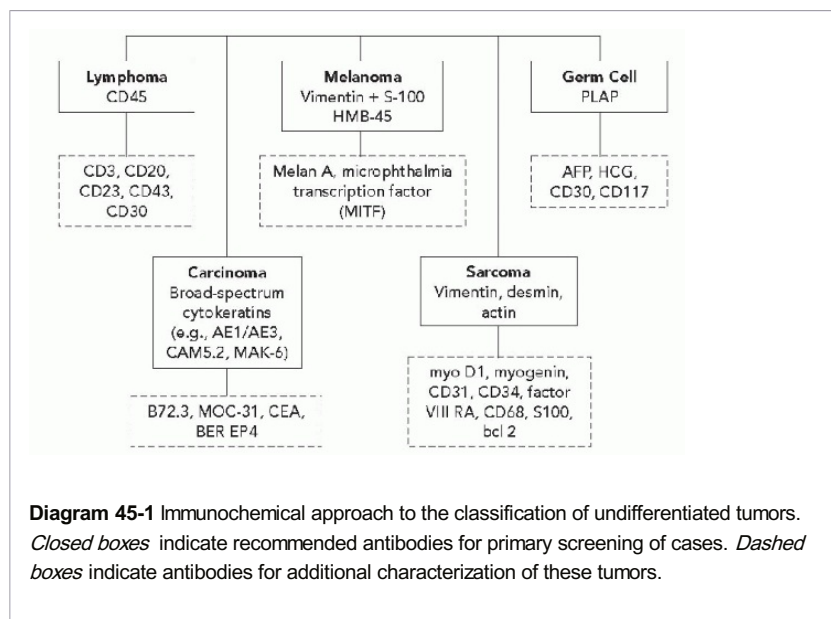

proteins (Osborn and Weber, 1983) (Table 45-3). Intermediate filaments are distinguished from other types of cytoskeletal filamentous structures ultrastructurally on the basis of size.

Microfilaments, which measure 5 to 15 nm, contain **actin** while the 25-nm microtubules contain **tubulin**. The intermediate filament family includes cytokeratins, vimentin, desmin, glial fibrillary acidic protein and the neurofilament proteins (see also Chap. 2).

The **cytokeratins** represent a complex family of approximately 20 proteins with molecular weights ranging from 44 to 68 kD (Moll et al, 1982; Gown and Vogel, 1984). These proteins, which are the major intermediate filament proteins of **normal and neoplastic epithelium**, can be identified in immunochemical formats using pancytokeratin antibodies which react with epitopes on multiple different molecular weight cytokeratin proteins or with chain specific antibodies which recognize one specific cytokeratin type. **Antibodies to cytokeratins are a critical component of antibody panels used for the classification of undifferentiated malignant tumors** (Diagram 45-1). As a first step, a cocktail of keratin antibodies should be used to demonstrate the possible epithelial nature of the tumor cells. Numerous combinations of antibodies have been recommended, but a **particularly useful mixture of antibodies** includes AE1/AE3, MAK-6 and CAM5.2 (DeYoung and Wick, 2000). This particular combination provides a spectrum of antibodies

P.1644

that react with keratins 1 through 8 and 14 through 19.

The cytokeratins are distributed in tissue specific patterns and both **primary and metastatic tumors tend to recapitulate the cytokeratin profiles of the tissues from which they are derived** (Wang et al, 1995). In some cases, patterns of cytokeratin expression are simple, while in others, complex patterns of cytokeratin expression are apparent. **Hepatocellular carcinomas**, for example, express **cytokeratins 8 and 18** while **multiple acidic and basic cytokeratins are found in squamous carcinomas**. In some instances, specific cytokeratins can be used to differentiate cells and tumors of particular types. For example, **Merkel cell tumors** are typically positive for cytokeratin 20 (in addition to other cytokeratins) while **small cell carcinomas** arising from other sites are cytokeratin 20 negative (Moll et al, 1992). In some instances, the **subcellular localization of cytokeratin** immunoreactivity may provide important diagnostic clues. For example, **small carcinomas often show a paranuclear dot-like staining pattern** while **mesotheliomas show a perinuclear net-like pattern of staining**.

There is now an extensive literature on **the distribution of cytokeratins in epithelial and non-epithelial tumors**. Generally, low molecular weight cytokeratins are present in simple and glandular epithelium while high molecular weight cytokeratins are typical of stratified epithelium. Wang et al as well as other authors have studied the coordinate expression of CK7 (54kD) and CK20 (46kD) in a large series of carcinomas of diverse origins (Wang et al, 1995; Chu et al, 2000; Tot, 1999; Blumenfeld et al, 1999) (Diagram 45-2). CK7 is distributed in a wide array of normal simple epithelia while CK20 is present in normal intestinal epithelium, gastric foveolar cells, urothelial umbrella cells and Merkel cells (Figs. 45-1 and 45-2). Tumors that coexpress both CK7 and CK20 include urothelial (transitional cell) carcinomas of the bladder and pancreatic adenocarcinomas while CK7 and CK20 negative tumors include hepatocellular, prostatic and renal cell carcinomas as well as squamous and neuroendocrine lung carcinomas.

The **CK7/CK20⁺ phenotype** is characteristic of adenocarcinomas of colorectal origin and

Merkel cell tumors while the **CK7⁺/CK20⁻ phenotype** is characteristic of tumors arising from a wide variety of other sites including the ovary, endometrium, breast and lung as well as mesotheliomas. Some carcinomas, including primary gastric adenocarcinomas typically show considerable heterogeneity in the expression patterns of cytokeratins 7 and 20.

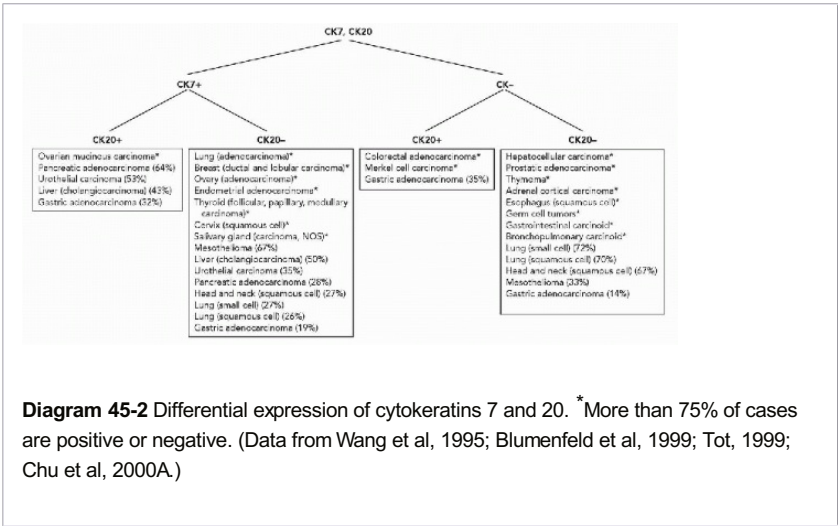

Cytokeratin 14 is an acidic cytokeratin which is restricted in its distribution to **the myoepithelial cells** of a variety of organs and basal cells of keratinized squamous epithelium (Chu et al, 2001). This marker is useful for the distinction of poorly differentiated squamous cell carcinoma from other poorly differentiated carcinomas. The studies of Chu et al have demonstrated that CK14 is present in most cases of squamous cell carcinoma (irrespective of their sites of origin or degrees of differentiation), neoplasms with focal squamous differentiation (endometrial and ovarian adenocarcinomas, mesotheliomas and transitional cell carcinomas), thymomas, myoepithelial components of salivary gland pleomorphic adenomas, and oncocytic tumors.

Coexpression of cytokeratins and other intermediate filaments is relatively common in carcinomas. For example, renal, endometrial and thyroid follicular neoplasms, as well as mesotheliomas, often coexpress cytokeratins and vimentin while medullary thyroid carcinomas, carcinoids, and pancreatic endocrine tumors may coexpress cytokeratins, vimentin and neurofilament proteins (Fig. 45-3). **Small cell desmoplastic tumors** often coexpress cytokeratins together with vimentin and desmin.

Cytokeratin expression has also been documented in a number of **sarcomas** including synovial and epithelioid sarcomas, leiomyosarcomas, rhabdomyosarcomas, chondrosarcomas

P.1645

and Ewing's tumor. Melanomas, particularly in metastatic sites, may also be positive for cytokeratins and occasional examples of malignant lymphoma, particularly of the Ki-1 and large cell types, have been reported to be positive for cytokeratins. Immunoreactivity for cytokeratins (AE1/AE3) also occurs in **glioblastoma multiforme** and this finding has been attributed to cross reactivity with epitopes present in the neoplastic glial cells (Morrison and Prayson, 2000). This is particularly problematic when the differential diagnosis includes metastatic poorly differentiated carcinoma. Oh and Prayson (1999) have shown that more than 50% of cases of glioblastoma multiforme are reactive for AE1/AE3 while only 1 of 23 cases contained cells that were positive for CAM5.2 and cytokeratins 7 and 20. In contrast, metastatic carcinomas were positive both for AE1/AE3 and CAM5.2.

Epithelial Membrane Antigen (EMA)

The milk fat globule membrane antigens represent a family of highly glycosylated proteins that are present on the apical membranes of breast epithelial cells. Antisera raised against these proteins include antibodies to the epithelial membrane antigen (EMA), a 70Kd glycosylated protein. EMA is not restricted in its distribution to breast epithelial cells but **is present in a very wide variety of epithelial cells** (Pinkus and Kurtin, 1985; Singh et al, 1995). In addition, a variety of **normal and neoplastic lymphoreticular cells** are reactive

P.1646

for EMA. **Perineural cells** are also reactive for EMA and positive reactions for this marker are present in nerve sheath tumors. Other tumors that are positive for EMA include **meningiomas** and certain **sarcomas** (epithelioid sarcoma, synovial sarcoma, chordoma, and chondrosarcoma) (Fig. 45-4).

Figure 45-2 Metastatic colonic adenocarcinoma in liver. A. Fine needle aspiration biopsy stained with the Papanicolaou stain. B. Immunoperoxidase stain for cytokeratin 20 in cell block demonstrates uniform positivity within the tumor cells.

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA) is a highly glycosylated protein which was detected initially in fetal gut and colonic adenocarcinomas (Fig. 45-5). There are considerable variations in staining patterns with different polyclonal and monoclonal CEA antibodies (Sheahan et al, 1990). In part, these differences are related to the presence of antibodies which cross-react with nonspecific cross-reacting antigens (NCA) that are widely distributed in tissues. In immunohistochemical preparations utilizing polyclonal antisera or monoclonal antibodies, the presence of reactivity in granulocytes indicates the presence of NCAs; however, monoclonal antibodies may be selected which lack immunoreactivity for NCAs. CEA is present in **a variety of normal cells and epithelial neoplasms** while melanomas, lymphoma, and sarcomas are negative.

Other Epithelial Markers

A variety of other epithelial markers have been developed for use in immunocytochemistry, including **B72.3, leu M1 (CD15), MOC-31, and BerEP4** which react with glycoprotein antigens (Diagram 45-3). The antigen recognized by B72.3 is a plasma membrane glycoprotein which is known as the tumor associated glycoprotein (TAG)-72. **B72.3 immunoreactivity** is present in a wide spectrum of carcinomas and some benign tissues (e.g., endometrium) but is absent in mesotheliomas, germ cell tumors and carcinomas of the adrenal cortex, liver, kidney, nasopharynx, and thyroid (Thor et al, 1986; Loy et al, 1993). Antibodies directed to leu M1 (CD15) react with neutrophils, monocytes, a subset of T cells and Reed Sternberg cells of classic Hodgkin's lymphoma (Arber and Weiss, 1993). In addition, **CD15 immunoreactivity** is present in approximately 75% of pulmonary adenocarcinomas and in a high proportion of carcinomas of the breast, kidney, and ovary, while mesotheliomas are typically negative (Sheibani et al, 1986). **BerEP4** represents another glycoprotein antigen which is expressed in a wide variety of epithelial malignancies including those of the GI tract, pancreatico-biliary tract, breast, ovary, and pancreas while mesotheliomas are usually negative (Fig. 45-5) (Sheibani et al, 1991). **MOC31**, which is discussed in further detail in the section on mesothelioma, is also positive in a wide range of epithelial malignancies but is nonreactive with germ cell malignancies, hepatocellular carcinoma, renal cell carcinoma and mesothelioma (Ruitenbeek et al, 1994). The expression of these markers, however, is often focal and a negative result may be related to sampling, a problem exacerbated in cytological specimens.

Other epithelial markers which have been used in the diagnostic setting include **CA125, CA19-9 and CA15-3**. **CA125 (OC125)** was initially defined in ovarian carcinoma cell lines and is most

commonly expressed in müllerian neoplasms, mesotheliomas and bile duct carcinomas, but may also be found in a small proportion of other tumor types, including those of the breast and thyroid (Bast et al, 1981; Kabawat et al, 1983; Haglund, 1986) (Fig. 45-6). **CA19-9** is present in carcinomas of the gastrointestinal tract, pancreato-biliary system, and müllerian origin; however, it is also expressed in a high proportion of other tumor types, including those of thyroid origin (Loy et al, 1993). **CA15-3** is expressed in many tumor types, including those of müllerian, gastrointestinal, pancreaticobiliary, renal, breast, and prostatic origin (Gatalica and Miettinen, 1994).

Transcription Factors as Selective Epithelial Markers

Transcription factors are proteins that bind to regulatory elements in the promoter and enhancer regions of DNA

P.1647

and **stimulate or suppress gene expression**. Transcription factors may be tissue specific or may be present in a variety of different tissue types. **Thyroid transcription factor-1 (TTF1)**, for example, is present in thyroid follicular cells and C-cells and is also present in the lung (Ordonez, 2000) (Fig. 45-7). The **adrenal 4 site/steroidogenic factor** is present in steroid-producing cells and in certain anterior pituitary cell types. The **pituitary transcription factor, Pit-1**, is present in certain cells of the anterior pituitary and is also present in the placenta (Kulig and Lloyd, 1996). In some instances, antibodies to transcription factors are of considerable value in determining the origins of tumors of unknown primary sites.

Figure 45-3 Metastatic renal cell carcinoma involving the lung. A. Fine needle aspiration biopsy stained with the Papanicolaou stain. B. Immunoperoxidase stain for EMA performed on destained slide demonstrates membrane positivity. C. Immunoperoxidase stain for cytokeratins 8 and 18 (CAM5.2) on a de-stained slide demonstrates cytoplasmic positivity. D. Immunoperoxidase stain for vimentin on a destained slide demonstrates focal cytoplasmic positivity. E. Histological section stained with hematoxylin and eosin demonstrates the typical features of renal cell carcinoma.

MESENCHYMAL MARKERS

Vimentin

Vimentin (MW57000) is the characteristic intermediate filament type of **mesenchymal cells** and **their corresponding tumors** (Battifora, 1991) (see Chap. 2, Diagram 45-2 and Fig. 45-4). The presence of immunoreactive vimentin in stromal and endothelial cells is considered an **index of adequate tissue fixation** and has been used as an internal "control" for this purpose. Vimentin is not restricted in its distribution to mesenchymal cells, however, since it is also found in a wide variety of normal and neoplastic epithelial and neural type cells. In some instance, mesenchymal cells and their tumors such as **thyroid** and **kidney** also contain cytokeratin proteins as discussed below (Miettinen, 1987; Suster, 2000). In mesenchymal cell

neoplasms, immunochemical analysis of other markers in addition to vimentin provides evidence of specific lines of differentiation.

Muscle Proteins

A variety of markers have been used to identify skeletal muscle differentiation **including desmin, muscle-specific**

P.1650

actin (HHF35), **skeletal muscle or sarcomeric actin, myoglobin, and creatine phosphokinase-MM** (Tsukada et al, 1987; Swanson and Wick, 1995; Suster, 2000) (Fig. 45-8). **Desmin** (MW-55,000) is the major intermediate filament type of muscle cells including cardiac, skeletal and smooth muscle cell types. Both desmin and muscle-specific actin are the most commonly used **markers for muscle tumors** (Truong et al, 1990; Rangdaeng et al, 1991). Although myoglobin is specific for skeletal muscle, its sensitivity for the diagnosis of rhabdomyosarcoma is low, particularly in poorly differentiated forms of the tumor (Tsokos, 1994). An alternative approach for the identification of cells with skeletal muscle differentiation involves the use of **myogenic regulatory proteins** (Li and Olson, 1992). **Myogenic regulatory proteins** play a key role in the commitment of primitive mesenchymal cells to a skeletal muscle lineage. Since these proteins are expressed earlier than structural proteins such as actin, myosin and desmin, they are particularly useful for the diagnosis of

rhabdomyosarcoma. **Antibodies to myoD1 and myogenin** have been used extensively for this purpose (Wang et al, 1995). In exceptional cases, **rhabdomyosarcomas may be positive for cytokeratins**, neurofilament triplet proteins, neuron-specific enolase, S100 protein and leu 7.

Figure 45-7 Metastatic poorly differentiated thyroid carcinoma in the lung. A. Cell block of fine needle aspiration biopsy stained with hematoxylin and eosin. B. Immunoperoxidase stain for thyroid transcription factor-1 in cell block demonstrates nuclear positivity.

Figure 45-8 Metastatic leiomyosarcoma of the bladder involving the sacrum. A. Hematoxylin and eosin stain of cell block. B. Immunoperoxidase stain for smooth muscle actin in cell block demonstrates cytoplasmic positivity.

Tumors derived from smooth muscle are reactive with antibodies to desmin and muscle-specific actin (HHF35). Moreover, these tumors are also reactive with antibodies to smooth muscle actin and caldesmon (Watanabe et al, 1999). In some cases, smooth muscle tumors are also reactive with cytokeratin antibodies (Suster, 2000).

Vascular Markers

The **factor VIII** related antigen (von Willebrand's factor) and **Ulex europaeus I (UEAI)** lectin have been used extensively for the evaluation of vascular tumors (Leader et al, 1986). Despite its high specificity, however, the factor VIII-related antigen has a relatively low sensitivity, particularly in poorly differentiated vascular tumors. UEAI, on the other hand, has high sensitivity but relatively low specificity since it reacts with a variety of epithelial cells. Although **thrombomodulin** was originally proposed as a marker for

P.1651

tumors with endothelial differentiation, it is expressed in a variety of other tumor types (Ordonez, 1997). More recently, **antibodies to CD31 and CD34** have been used for the identification of endothelial differentiation (Miettinen et al, 1994; von der Rijn and Rouse, 1994). It should be recognized, however, that a variety of soft tissue neoplasms, including dermatofibrosarcoma protuberans, solitary fibrous tumor, GI stromal tumors and peripheral nerve sheath tumors are also reactive for CD34. CD31, on the other hand, may be expressed weakly in some carcinomas and mesotheliomas (Suster, 2000).

Other Markers

Fibrohistiocytic tumors are **vimentin** positive and are variably reactive for **alpha-1-antitrypsin**, **alpha-1-antichymotrypsin** and **CD68** (Swanson and Wick, 1995). Occasional fibrohistiocytic tumors also exhibit immunoreactivity for **cytokeratins**. **Neurogenic tumors**, including Schwannomas, neurofibromas and malignant peripheral nerve sheath tumors are typically positive for **S100 protein** and are variably reactive for **leu 7** (Wick et al, 1987; Johnson et al, 1988). EMA may also be present, particularly in plexiform neurofibromas. Both **liposarcomas**

and **chondrosarcomas** are typically positive for S100 protein while osteogenic sarcomas are often positive for **osteonectin**. **Sarcomas which consistently exhibit cytokeratin positivity** include synovial and epithelioid sarcomas (Swanson and Wick, 1995; Suster, 2000).

Chordomas are also typically positive for cytokeratins and EMA but also react with antibodies to S100 protein.

Bcl-2 expression was originally described in malignant lymphomas but was subsequently identified in a wide variety of other tumors including certain carcinomas and sarcomas (Joensuu et al, 1994; Nakamura et al, 1997; Nakanishi et al, 1997). As noted by Suster (2000), the most useful applications of this antibody are in the diagnosis of the **monomorphic variant of synovial sarcoma, solitary fibrous tumors, and gastrointestinal stromal tumors (GIST)**. Other **connective tissue neoplasms** that exhibit bcl-2 positivity include spindle cell lipoma, dendritic myxofibrolipoma Kaposi's sarcoma, benign and malignant nerve sheath tumors, fibrosarcoma, low grade myxofibrosarcoma, malignant fibrous histiocytoma and dermatofibrosarcoma protuberans. **CD99** is another marker which is expressed commonly in **soft tissue tumors**, including mesenchymal chondrosarcoma, synovial sarcoma, leiomyosarcoma, malignant fibrous histiocytoma and solitary fibrous tumor (Renshaw, 1995).

CD117 (C-kit) has emerged as an **important marker** for the interstitial cells of Cajal and the **gastrointestinal stromal tumors** which are thought to arise from these cells (Kindblom et al, 1998; Suster, 2000). However, c-kit expression also occurs in **acute myeloid leukemia, mast cell disease, malignant melanoma, Ewing's tumor, and a variety of carcinomas**, including those of the breast, endometrium, lung, ovary and thyroid. Among **spindle cell tumors**, c-kit expression has been documented in leiomyosarcomas, dermatofibrosarcoma protuberans, hemangiopericytoma, malignant fibrous histiocytoma, and synovial sarcoma, among others.

LYMPHOID MARKERS

The malignant lymphomas include a heterogeneous group of neoplasms which have been classified into Hodgkin and non-Hodgkin types (see Chap. 31). The subclassification of these neoplasms depends on distinctive architectural, cytological, immunophenotypic and molecular features (Hughes et al, 1998; Jaffe-Perez et al, 1999). Immunophenotypic methods include flow cytometry and immunocytochemistry (see Chap. 47 and Diagram 45-2). The advantages of immunocytochemistry, particularly when applied to cytospin preparations, are the requirements for relatively small numbers of cells and the ability to directly correlate cellular morphology with patterns of marker expression (Simsir et al, 1999). Disadvantages of immunocytochemistry on cytospin preparations include the relatively low sensitivity of detection of small monoclonal populations and the inability to provide quantitative data. In institutions with considerable experience in immunocytochemistry and cytological specimens, the rate of correlation between flow cytometry and immunocytochemistry is as high as 98% (Simsir et al, 1999). In 98 cases reported by Simsir et al, 11% could not be phenotyped by flow cytometry and 4% could not be phenotyped by immunochemistry. While the precise subclassification of malignant lymphomas cannot be achieved in cytological preparations alone, their distinction from other types of poorly differentiated malignancies and reactive lymphoid proliferations can be accomplished in cytological samples.

One of the most useful markers for this purpose is **leukocyte common antigen (CD45)** (Chu et al, 2000) (Fig. 45-9; see Diagram 45-2). CD45 is a 200 kD glycoprotein which is present in the plasma membranes of B and T lymphocytes, monocytes and granulocytes but which is absent from erythrocytes and megakaryocytes. **CD45 is present in the vast majority of malignant lymphomas** although its reactivity may be weak or absent from plasmacytic neoplasms, anaplastic large cell lymphomas, Reed Sternberg cells in Hodgkin lymphomas of mixed cellularity, and nodular sclerosing and lymphocyte depleted Hodgkin lymphoma. Reed-Sternberg cells of lymphocyte-predominant Hodgkin lymphomas are usually positive. A specificity of 100% and a sensitivity of 90% have been reported for antibodies to CD45.

The immunophenotypic identification of B-cell lymphomas is accomplished by the demonstration of **B-cell cell markers** and in some cases (small lymphocytic lymphoma and mantle cell lymphoma) by the concurrent expression of CD5. The cases which are most amenable to cytological diagnosis are those that consist of a monomorphic cell population that does not require architectural assessment. Cases of follicular lymphoma, marginal zone lymphoma, mantle zone lymphoma, and Hodgkin lymphoma often require histological

P.1652

assessment (see Chap. 31). B-cell lineage is most effectively accomplished by the application of **CD19, CD20, CD22, and CD45RA** antibodies (Fig. 45-9). In addition to these markers, the diagnosis of B-cell **lymphomas and their differentiation from reactive processes requires the demonstration of light chain restriction** by staining for kappa and lambda light chains. Monoclonality is defined as a kappa:lambda ratio of more than 6:1 or a lambda:kappa ratio of more than 4:1 (Sneige, 1990). In addition to CD20, antibodies that are of particular value in the

categorization of mature B-cell lymphomas include **CD43, CD5, CD10, CD23, and cyclin D1**. Positive staining for CD43 and CD5 is characteristic of small lymphocytic lymphoma and mantle cell lymphoma. CD23 is consistently expressed in small lymphocytic lymphomas but is present in less than 20% of mantle cell lymphomas and marginal zone lymphomas. Among lymphomas, CD10 expression is limited to those of follicular type while cyclin D1 positivity is characteristic of mantle cell lymphomas.

Figure 45-9 Large cell lymphoma. A. Immunoperoxidase stain for leukocytes common antigen (CD45) performed on a Papanicolaou stained aspirate demonstrates positive staining of the plasma membranes. B. Immunoperoxidase stain for CD20 demonstrates a similar pattern of staining. C. Immunoperoxidase stain for CD3 demonstrates a population of non-neoplastic T-cells. D. Hematoxylin and eosin stained section of a subsequent excisional biopsy demonstrates the typical features of a large cell lymphoma.

The **diagnosis of T-cell lymphomas** is considerably more difficult than the diagnosis of B-cell lymphomas in cytological preparations. The identification of T-cell lymphomas requires the demonstration of appropriate T-cell markers with dropout of certain of the antigens. The presence of **terminal transferase** is characteristic of lymphoblastic lymphomas. For further extensive discussion of these issues, see Chapter 31.

NEURAL AND NEUROENDOCRINE MARKERS

Neurofilaments

The neurofilaments are composed of heteropolymers of three different subunits with molecular weights of 70, 170, and 200 kD, corresponding to low (L), medium (M), and high (H) molecular weight subunits (Shaw and Weber, 1982; Kimura et al, 1990; Morrison and Prayson, 2000) (see Diagram 45-3). Each isoform differs by the extent of phosphorylation. The neurofilaments represent the major intermediate filaments of mature and developing neurons, paraganglionic cells and certain normal neuroendocrine cells. In neurons, NF-L and NF-M are present in immature cells with neuronal differentiation while NF-H is present in mature neurons. **These proteins are also expressed in tumors with evidence of neuronal differentiation and are present in varying degrees in neuroendocrine tumors of epithelial type which also contain cytokeratins.** Neuroendocrine

P.1653

tumors of nonepithelial type, such as paragangliomas and neuroblastomas, are positive for neurofilaments but negative for cytokeratins (Wick, 2000; DeLellis, 2001).

Cytosolic Markers

Neuron-specific enolase (NSE) is a glycolytic dimeric enzyme composed of alpha, beta and gamma subunits. Neurons and neuroendocrine cells contain the gamma-gamma form of the enzyme while other forms of enolase are present in a wide variety of normal and neoplastic cells (Tapia et al, 1981). Since NSE is a cytosolic marker, it is usually positive even in those cells and tumors that contain few or no secretory granules. Although most antibodies to neuron specific enolase provide a high level of sensitivity for the detection of **cells with neural/neuroendocrine differentiation**, their specificity is low (Fig. 45-10) (Haimoto et al, 1985). Monoclonal antibodies to NSE, on the other hand, exhibit a higher specificity but lower sensitivity (Thomas et al, 1987). **Protein gene product 9.5 (PGP 9.5)** is another cytosolic marker that separates ubiquitin from other proteins (Rode, 1983). This marker is present in a wide variety of neuroendocrine cells and tumors but its specificity as an immunochemical

marker is low.

Chromogranins

The chromogranins include a family of proteins which form the most abundant constituent by weight of the **chromaffin granules** (Lloyd and Wilson, 1983) (Fig. 45-11). The chromogranin family includes **chromogranin A, chromogranin B, and secretogranin II**, in addition to other chromogranin types (**secretogranin IV and V**) (Fahrenkamp et al, 1995). There is differential expression of chromogranins in normal cells and corresponding neoplasms of differing origins. For example, chromogranin A predominates in mid-gut carcinoids while chromogranin B is the predominant granin of hindgut neuroendocrine cells and carcinoids. The extent of chromogranin positivity generally parallels the numbers of intracytoplasmic secretory granules.

Figure 45-10 Small cell bronchogenic carcinoma. A. ThinPrep stained with Papanicolaou stain. B. Immunoperoxidase stain for neuron specific enolase on ThinPrep. The tumor cells were also positive for EMA and synaptophysin.

Synaptophysin

Synaptophysin is a 38 kD protein present in synaptic vesicles of neurons, neuroendocrine cells and many neuroendocrine tumors (Gould et al, 1986) (see Fig. 45-11). Synaptophysin, however, is not entirely specific for neuroendocrine tumors. Adrenal cortical neoplasms, for example, may exhibit synaptophysin reactivity (Komminoth et al, 1995).

Peptide Hormones and Amines

The **hormonal content of neuroendocrine cells** and tumors can be demonstrated effectively with monoclonal antibodies using a variety of staining formats (DeLellis, 2001). Although tumors of specific sites have characteristic patterns of hormone expression (see Chap. 39 as an example), the presence of a particular hormone does not allow absolute predication of the site of origin of a metastatic neoplasm. **Calcitonin**, for example, is present in medullary thyroid carcinomas, small cell lung carcinomas, bronchopulmonary carcinoids, and thymic and prostatic neuroendocrine tumors. **Somatostatin** shows a similar widespread distribution.

Other Markers

Leu 7 (CD57) reacts with lymphocytes with natural killer and killer cell activity, some neural and neuroendocrine cells and a wide variety of neoplasms including small cell carcinomas, neuroendocrine tumors, and carcinomas of the thyroid and prostate (Arber and Weiss, 1995).

GLIAL MARKERS

Glial fibrillary acidic protein (GFAP) (52 kD) is **the major intermediate filament of fibrous and protoplasmic astrocytes and their corresponding neoplasms** (Eng et al, 1971). This protein is also present in some ependymal cells, cerebellar radial glial cells and Müller cells of the retina.

P.1654

While mature oligodendrocytes do not contain GFAP, cells that transiently express GFAP and myelin basic protein have been described. **Staining intensity in glial tumors is inversely proportional to tumor grade** (Schiffer et al, 1986; Morrison and Prayson, 2000). GFAP is also present in nonmyelinated Schwann cells, certain cells of the pituitary and breast and in tumors not considered to be of glial origin including mixed tumors of salivary gland and skin origin, nerve sheath tumors and chordomas.

Figure 45-11 Pancreatic endocrine tumor. Cell block of fine needle aspirate stained (A) with hematoxylin and eosin, (B) with immunoperoxidase stain for chromogranin, and (C) with synaptophysin both showing cytoplasmic granularity.

S100 protein (MW20-25 kD) is a calcium binding protein composed of alpha and beta subunits (Jensen et al, 1985). The exact function of this protein is, however, unknown. S100 protein is present in a wide variety of cells in the nervous system including astrocytes, oligodendrocytes, ependymal cells, Schwann cells, and some neurons and in their corresponding neoplasms. At the cellular level, it is present both in the nuclei and in cytoplasm. This antigen is present in a **wide variety of other normal cell types**, including Langerhans cells, and it is present in a very wide variety of tumor types including melanomas and carcinomas (Nakajima et al, 1982).

MELANOMA MARKERS

The diagnosis of malignant melanoma, particularly those tumors of amelanotic type, is challenging both in histological and cytological materials (Gupta and Lallu, 1997) (see Diagram 45-1). Numerous antibodies have been assessed for the diagnosis of this tumor, but none is absolutely specific. In most studies, **a panel of antibodies directed to vimentin, S100 protein, HMB45, and MART1** (melanoma-associated antigen recognized by T cells) is used to establish the diagnosis of melanoma (Fig. 45-12; see Diagram 45-2).

Vimentin is strongly expressed in melanomas, but by itself this marker is of little diagnostic value since it is expressed in a wide variety of tumors (Angeli et al, 1988). Although initial studies indicated that melanomas were negative for cytokeratins, more recent studies employing histological and cytological materials have revealed **cytokeratin positivity** in variable numbers of cases, particularly in metastatic sites. In fine needle aspirates, for example, cytokeratin positivity has been found in up to 25% of evaluable cases (Banks et al, 1995).

S100 protein is the most sensitive marker for the diagnosis of melanoma; however, this protein is widely expressed in a variety of normal cells and neoplasms of diverse origins. Both in cytological and histological samples, **positive staining is present, both within the nucleus and the cytoplasm**. However, the value of S100 as a melanoma marker appears to be somewhat limited in alcohol-fixed FNA specimens (Simmons and Martin, 1991).

HMB45 has a higher level of specificity but lower sensitivity than S100 (Simmons and Martin, 1991). The staining is typically granular and is present **within the cytoplasm**. Desmoplastic and spindle cell melanomas are usually negative for HMB45. Other lesions that are reactive for HMB45

P.1655

include angiomyolipoma and pulmonary lymphangioleiomyomatosis (Zamecnik, 1999).

Figure 45-12 Metastatic malignant melanoma involving the lung. *A.* Diff-Quik stain. *B.* Immunoperoxidase stain for S100 protein demonstrates nuclear and cytoplasmic positivity. *C.* Immunoperoxidase stain for Melan-A (A103) demonstrates cytoplasmic positivity. *D.* Immunoperoxidase stain for HMB45 demonstrates cytoplasmic positivity.

MART1 is a melanocyte specific antigen that is widely expressed in malignant melanomas. Two clones have been developed (M27C10 and A103) and both have similar patterns of reactivity in melanocytic lesions (Beatty et al, 1997; Jungbluth et al, 1998; Fetsch et al, 1999). The **antibody A103** also cross-reacts with an epitope present in steroid producing cells. In a comparative **study of effusions**, melanoma cells were positive for MART 1 in 78% of cases, HMB45 in 81% and S100 in 81% of cases. Coexpression of all three markers was observed in 63% of cases (Beatty et al, 1997). Fetsch et al (1999) demonstrated that the MART 1 antibody was more sensitive than HMB45 for the **diagnosis of melanoma in FNA samples**. Blessing et al (1998) compared the antibodies to Melan A, S100 and HMB45 in histological preparations and concluded that Melan A was more sensitive than HMB45, but was of less value than S100 for the diagnosis of **desmoplastic and spindle cell melanomas**. The **clear cell sarcoma of soft parts** (melanoma of soft parts) also exhibits positivity for S100 and HMB45.

The **microphthalmia transcription factor (MitF)**, which is essential for the development and survival of melanocytes, has been used in immunochemical formats as a marker for melanomas and benign melanocytic lesions (King et al, 1999, 2001; Koch et al, 2001). Of particular importance is the fact that **MitF may be positive in tumors that are HMB45 and S100 negative** (King et al, 1999, 2001). King et al have demonstrated that MitF is a sensitive and specific marker for melanomas of all types, except for the desmoplastic variant. In their series, only 1 of 14 (7%) desmoplastic melanomas was MitF-positive. Koch et al (2001), on the other hand, reported MitF immunoreactivity in 11 of 20 (55%) of desmoplastic melanomas in their series. Other tumors reported to have MitF positivity are neurofibromas (20%), atypical fibroxanthomas (10%), clear cell sarcomas (70%), and melanotic schwannomas (100%). In **renal tumors**, MitF has been reported in approximately 75% of **angiomyolipomas** and 2 of 23 non-angiomyolipomatous tumors, including 1 renal cell carcinoma and 1 liposarcoma (Zavala-Pompa et al, 2001). An additional benefit of MitF is that the staining is nuclear and this feature is particularly helpful in heavily pigmented cells.

GERM CELL MARKERS

The correct identification of germ cell tumors is critical for the design of appropriate management strategies for affected patients. One of the most useful markers is **placental alkaline**

P.1656

phosphatase (PLAP) which is expressed in the majority of germ cell tumors of all **types with the exception of teratomas** (Wick et al, 1987; Bailey et al, 1992) (see Diagram 45-1). Immunoreactivity for PLAP is typically seen in the cell membranes of tumor cells although occasional cases may also exhibit cytoplasmic staining. However, PLAP is also present in a variety of other tumor types and, in fact, was first described in a patient with bronchogenic carcinoma as the Regan isoenzyme of alkaline phosphatase.

Human chorionic gonadotropin (HCG) is absent from seminomas with the exception of occasional syncytial trophoblastic elements which may be scattered within the tumor (Niehans et al, 1988). Similar HCG positive cells may be identified in embryonal carcinomas, but choriocarcinomas generally stain intensely for HCG. **Alpha-fetoprotein immunoreactivity** is generally present in **embryonal carcinomas and yolk sac tumors**, but is absent from seminomas.

Although early studies indicated that seminomas were negative for **cytokeratins**, more recent studies have demonstrated cytokeratin immunoreactivity in 20% to 50% of cases using antibodies AE1/AE3 and CAM5.2 and is most frequently present in the form of **a dot-like paranuclear pattern of staining**. In a recent study, Tickoo et al (2002) demonstrated CAM5.2 reactivity in 20% of seminomas. Thirteen of the cases had only dot-like staining while 4 cases showed rare single cells with membrane type staining and 2 cases had both dot-like and membrane predominant staining. In this series, 2 of 14 seminomas with atypia were positive for CAM 5.2 and both had membrane staining in rare single cells. All cases with dot-like staining belonged to the usual seminoma group. **Embryonal carcinomas, yolk sac tumors, and choriocarcinomas are more consistently and extensively cytokeratin positive.**

The studies of Ferreiro et al (1994) demonstrated that CD30 is present in most embryonal carcinomas but is negative in seminomas and yolk sac tumors. More recent studies, however, indicate that scattered CD30 positive cells may be present in occasional yolk sac tumors and seminomas (Hittmair et al, 1996). In the seminoma group, **CD30 immunoreactivity** was more likely to occur in seminomas with atypia rather than in the usual seminomas. Suster et al have demonstrated **consistent differences in patterns of staining in mediastinal and gonadal germ cell tumors** (Suster et al, 1998). For example, cytokeratin positivity was present in a dot-like pattern in 80% of mediastinal seminomas but in only 20% of testicular primaries while PLAP was more commonly expressed in mediastinal than in testicular primaries.

A variety of other markers have been studied in germ cell tumors **including ferritin, alpha-1-antitrypsin, and the c-kit gene product (CD117)**. c-kit is present both in a high proportion of **testicular seminomas and ovarian dysgerminomas** within the plasma membranes of the tumor cells. Nonseminomatous and germ cell tumors, on the other hand, are either c-kit-negative or show focal cytoplasmic staining in occasional cells (Tsumura et al, 1994; Izquierdo et al, 1995; Strohmeyer et al, 1995). A higher proportion of seminomas with atypia are c-kit negative as compared to usual seminomas (Tickoo et al, 2002).

SMALL ROUND CELL TUMOR MARKERS

The small round cell tumors encompass a heterogeneous array of neoplasms which include **malignant lymphomas, Ewing's sarcoma/peripheral neuroectodermal tumor, rhabdomyosarcoma, Wilms' tumor, small cell neuroendocrine carcinoma, neuroblastoma and the desmoplastic small round cell tumor** (Table 45-4). Distinction of these various tumor types is of paramount importance because of differences in therapeutic approaches. The immunohistochemical features of rhabdomyosarcoma and malignant lymphoma have been discussed previously.

Neuroblastomas commonly express the **NF-L protein**; however, some cases are positive with antibodies to the NF-M and NF-H proteins (Molenaar et al, 1990). Neuron specific enolase is present in virtually all neuroblastomas. Additional markers that are positive in these tumors include chromogranins and secretogranins, synaptophysin, ganglioside D2, protein gene product 9.5, microtubule (**MAP1, MAP2**) and tau proteins and certain neuroblastoma directed monoclonal antibodies, including **UJ13A** and **HSAN1.2** (Artlieb et al, 1985; Wiedemann et al, 1985; Brook et al, 1989; Oppedal et al, 1989; Moss et al, 1991; Sariola et al, 1991). CD99 is typically negative in neuroblastomas (Stevenson et al, 1994).

Wilms' tumor is typically positive for vimentin in the blastemal elements and these cells may also express cytokeratins. The epithelial elements are cytokeratin positive while vimentin is negative. The stromal cells are vimentin positive and may exhibit desmin immunoreactivity in the presence of muscle differentiation. These tumors also exhibit positivity for the **Wilms' tumor (WT) gene product** (Grubb et al, 1994).

Ewing's sarcoma/peripheral neuroectodermal tumors (ES/PNET) are generally positive for **neurofilament proteins** in addition to a variety of other neural markers including neuron specific enolase, synaptophysin, leu 7 and protein gene product 9.5. In some cases, secretogranin II immunoreactivity is evident, but this is variable. The **CD99 antibody**, which reacts with a plasma membrane protein product of the MIC2 gene, is typically positive in ES/PNET. **CD99** can be demonstrated in histological preparations and in a variety of cytological materials (Halliday et al, 1998). The combination of CD99 and vimentin positivity is common; however, CD99 positivity is not specific for ES/PNET. Immunoreactivity for CD99 is also present in lymphoblastic lymphomas, some rhabdomyosarcomas, synovial sarcomas and the blastemal elements of Wilms' tumors.

The **desmoplastic small round cell tumor** is typically positive for cytokeratins EMA vimentin, desmin and neuron specific enolase (Fig. 45-13). Desmin immunoreactivity has a dot-like pattern of distribution. Using the antibody WT (C19), the tumors are consistently positive for the Wilms' tumors (WT) gene product (Barnoud et al, 2000). In the same study, 71% of Wilms' tumors showed positivity while rare positive staining was present in 12% of rhabdomyosarcomas. There were no positive cases of Ewing's tumor or neuroblastoma. CD99

is usually negative but some cases

P.1657

may show diffuse cytoplasmic staining. Stains for chromogranins and synaptophysin are most often negative.

TUMORS OF SPECIFIC SITES

Breast

There are currently **no markers that are entirely specific for normal or neoplastic breast epithelial cells**. Although **casein, alpha-lactalbumin, gross cystic disease fluid protein (GCDFP15)** and **epithelial membrane antigen (EMA)** were originally thought to be specific markers, each **is also present in a variety of other cell types**. Epithelial membrane antigen is present in a very wide variety of normal and neoplastic epithelial cell types, as discussed in a previous section. Gross cystic disease fluid protein is present in normal apocrine glands, serous cells of normal salivary glands and bronchial submucosal glands. This protein is

P.1658

expressed in 72% of invasive ductal carcinomas and in 53% of invasive lobular carcinomas (see Diagram 45-3). The **rates of specificity and sensitivity and the predictive value of a positive result for GCDFP15** were 95%, 74%, and 74%, respectively, as reported in a large study by Wick et al (1989). Corresponding parameters for alpha-lactalbumin were 50%, 50%, and 23%. Other authors, however, have found a low sensitivity for GCDFP15 in breast carcinoma. In the study reported by Mazoujian et al (1989), 55% of breast carcinomas were positive for GCDFP15. In this series, only 23% of carcinomas without apocrine features stained positively while only 5% of medullary carcinomas were positive. Tumors that were most likely to be positive included carcinomas with apocrine features (75%), infiltrating signet ring cell carcinomas (90%) and intraductal carcinomas (70%). In addition to breast carcinomas, the major tumor types positive for GCDFP15 were carcinomas of salivary glands, sweat glands, and prostate. Rarely, ovarian, renal and urothelial carcinomas may express positivity for this marker. Immunochemistry for GCDFP15 has also been analyzed in cytological preparations. In the study reported by Fiel et al (1996), 13 of 23 primary, recurrent or metastatic breast

carcinomas were positive for GCDPF15 while none of 20 non-breast carcinomas was positive.

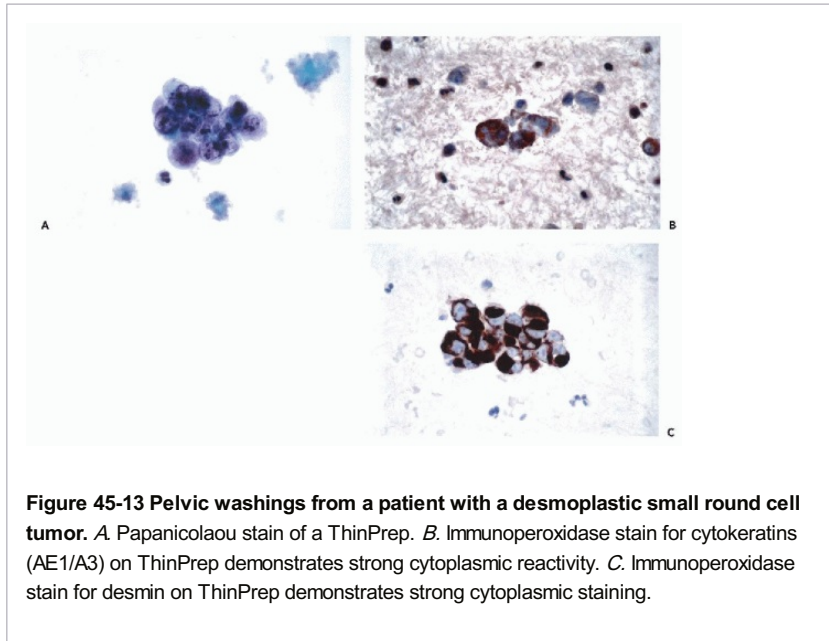

Figure 45-13 Pelvic washings from a patient with a desmoplastic small round cell tumor. A. Papanicolaou stain of a ThinPrep. B. Immunoperoxidase stain for cytokeratins (AE1/A3) on ThinPrep demonstrates strong cytoplasmic reactivity. C. Immunoperoxidase stain for desmin on ThinPrep demonstrates strong cytoplasmic staining.

Strong positivity for **estrogen** and **progesterone receptors** has also been used as a marker for the identification of breast carcinoma in metastatic sites (Figs. 45-14 and 45-15). However, steroid receptor positivity is not restricted to breast cancers and may also be found in other gynecological malignancies and a variety of other tumor types, including those of thyroid origin. Deamant et al (1993) have examined the **predictive value of estrogen receptor positivity** in a large cohort of carcinomas of the breast and a variety of other sites. Estrogen receptor positivity was noted in 88% of lobular carcinomas and 66% of ductal carcinomas. In nonbreast tumors, positivity was present in 53% of endometrial carcinomas, 46% of thyroid carcinomas, and 45% of ovarian carcinomas. There was no evidence of estrogen receptor positivity in 276 gastric carcinomas or 151 pulmonary carcinomas; however, sweat gland tumors may also exhibit positivity for estrogen receptor (Swanson et al, 1991). Other tumors which may be positive for estrogen or progesterone receptors include meningiomas, some sarcomas, and neuroendocrine tumors of the lung, skin, gastrointestinal tract and pancreas (Viale et al, 1992; Bacchi et al, 1997).

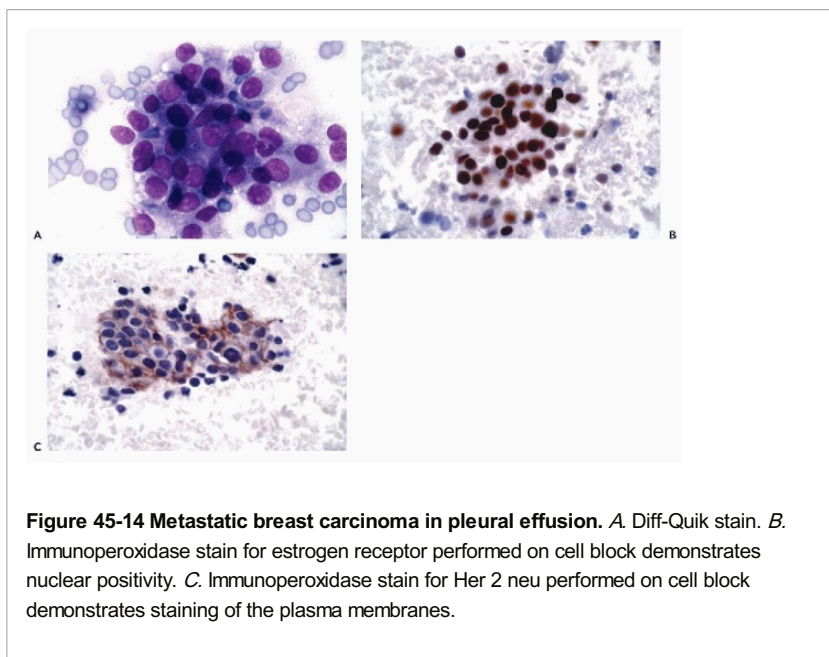

Figure 45-14 Metastatic breast carcinoma in pleural effusion. A. Diff-Quik stain. B. Immunoperoxidase stain for estrogen receptor performed on cell block demonstrates nuclear positivity. C. Immunoperoxidase stain for Her 2 neu performed on cell block demonstrates staining of the plasma membranes.

The **monoclonal antibody, CA15-3**, was originally developed as a breast specific marker. However, subsequent studies revealed a widespread distribution in a variety of different carcinomas including those of the lung, kidney and bladder, as discussed in a previous section.

In addition to epithelial cells, **myoepithelial cells** have also been studied **extensively in**

normal and neoplastic breast tissues using antibodies to S100 protein and smooth muscle actin. The presence of myoepithelial cells has been used to distinguish papillomas (positive) from papillary carcinomas (negative) and to identify foci of invasion in situ carcinomas in histological sections. Antibodies to muscle

P.1659

specific actin in smears and cell block consistently highlighted myoepithelial cells in fibroadenomas and cases of atypical hyperplasia while invasive carcinomas failed to show the reticulated pattern of staining seen in benign breast lesion (Masood et al, 1995). Dabbs and Gown (1999) have also studied the distribution of myoepithelial cells in fine needle aspiration biopsies of the breast using antibodies to smooth muscle myosin heavy chain and calponin. These studies have demonstrated that **calponin**-positive myoepithelial cells were commonly associated with in situ ductal carcinomas although, occasionally, they were discontinuous or entirely absent and that invasive carcinomas were devoid of myoepithelial cells. **Bipolar stromal cells, on the other hand, did not correspond to myoepithelial cells and were negative for calponin and smooth muscle myosin heavy chain.**

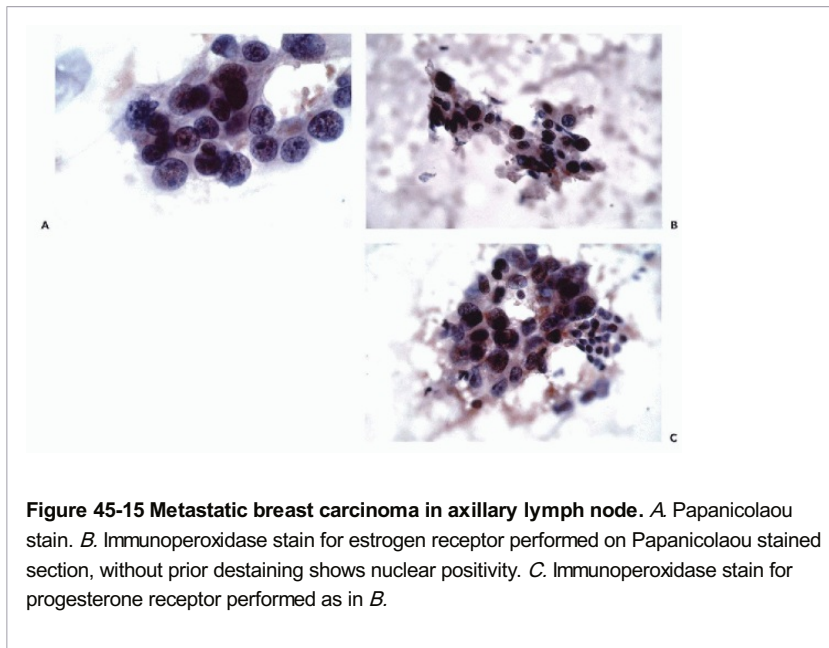

Figure 45-15 Metastatic breast carcinoma in axillary lymph node. A. Papanicolaou stain. B. Immunoperoxidase stain for estrogen receptor performed on Papanicolaou stained section, without prior destaining shows nuclear positivity. C. Immunoperoxidase stain for progesterone receptor performed as in B.

The **distinction of metastatic breast carcinomas from primary pulmonary carcinomas** is a formidable problem using cytological preparation. Harlamert et al (1998) demonstrated that lung adenocarcinomas were CK7⁺/CK20⁻ in 95% of cases and exhibited thyroid transcription factor 1 (TTF1) reactivity in 76%. **Breast carcinomas were consistently TTF1 negative and also exhibited a CK7⁺/CK20⁻ phenotype.**

Lung

Carcinomas of all cell types are **positive for cytokeratins**. Both adenocarcinomas and squamous cell carcinomas demonstrate diffuse cytoplasmic reactivity while oat cell carcinomas generally exhibit a dot-like paranuclear staining pattern. With respect to cytokeratins 7 and 20, most nonsmall cell carcinomas are CK7⁺/CK20⁻ as are bronchioloalveolar carcinomas (Wang et al, 1995) (see Fig. 45-1). Most squamous carcinomas are CK7⁺/CK20⁻ as are most small cell carcinomas. CEA is also present in all pulmonary tumor types, but small cell carcinomas are generally less reactive than adenocarcinomas and squamous carcinomas. EMA is expressed in adenocarcinomas of the lung but is not helpful in the distinction of primary from metastatic adenocarcinomas in this site. **Surfactant protein B precursor** is present in 51% of pulmonary adenocarcinomas and 20% of large cell carcinomas (Khor et al, 1999) (see Fig. 45-6). It is also present in **non-neoplastic pneumocytes type II** (see Chap. 19). **Thyroid transcription factor 1** is present in 75% of lung adenocarcinomas, 10% of squamous cell carcinomas and 26% of large cell carcinomas (Fig. 45-16). In contrast, TTF1 is present in less than 1% of nonpulmonary adenocarcinomas. This marker is, therefore, particularly **useful in the distinction of primary pulmonary adenocarcinomas from metastatic adenocarcinomas** to the lung and mesotheliomas (Harlamert et al, 1998; Khor et al, 1999).

Small cell carcinomas, large cell neuroendocrine carcinomas, and typical and atypical carcinoids are usually positive for **neuron-specific enolase** and are variably positive for **chromogranins, synaptophysin** and a variety of peptides such as **gastrin-releasing peptide**. Carcinoids are

more consistently positive for chromogranins and synaptophysin than are small cell carcinomas. **TTF1** is present in 75% of large cell neuroendocrine carcinomas, 30% of typical carcinoids, 100% of atypical carcinoids and 95% of small cell carcinomas (Folpe et al, 1999; Ordonez, 2000). This marker is also useful in the distinction of metastatic pulmonary small cell carcinomas from **Merkel cell carcinomas** which are typically negative for TTF1. Occasional extra pulmonary small cell carcinomas, however, may show reactivity for TTF1 while extrapulmonary non-small-cell neuroendocrine tumors are negative for TTF1 (Agoff et al, 2000).

Mesothelioma

The **distinction of malignant mesothelioma and metastatic adenocarcinoma in body cavity fluids** is a formidable challenge (see Chap. 26). The simplest and least expensive test is **mucicarmine stain** that is positive in most adenocarcinomas and negative in mesotheliomas (see Chap. 26). Since the late 1970s, a **variety of polyclonal antisera and monoclonal antibodies** have been developed using cultured human mesothelial cells (Singh et al, 1979), malignant mesothelioma cell lines (O'Hara et al, 1990) or purified recombinant proteins such as the NH2 terminal region of the Wilms' tumor suppressor gene protein as the immunogens (Amin et al, 1995) and the AMAD2 antiserum which is directed against a recombinant cytoplasmic mesothelial protein (Donna et al, 1997). Many of these **antibodies are effective only in frozen sections, lack mesothelioma specificity or react primarily with the epithelial type of malignant mesothelioma** (Donna et al, 1997) (Table 45-5; see Diagram 45-3).

Negative Markers

Until recently, a variety of "negative" markers, which were present in adenocarcinomas but not in mesotheliomas, formed the basis for the diagnosis of mesothelioma. One of most extensively utilized negative markers is CEA. Initial studies reported by Wang et al indicated that CEA was present in 100% (12 of 12) of adenocarcinomas but in no cases of mesothelioma (0 of 9). Since that time, numerous additional studies have reported that up to 45% of mesotheliomas may express CEA, particularly when polyclonal antisera are used. Moreover, additional studies showed that up to 75% of adenocarcinomas may be negative for CEA. Despite these wide variations, which are undoubtedly related to technical variables, **CEA remains a valuable negative marker**, particularly when using monoclonal antibodies under highly controlled conditions (Wick et al, 1990; Riera et al, 1997). The monoclonal antibody B72.3 has also been used as a negative marker (see Fig. 45-5). Initial studies reported by Lafebvre et al (1985) demonstrated that B72.3 was present in 85% of lung adenocarcinomas and in 20% of mesotheliomas which generally exhibited weak staining. In a larger series, Ordonez (1999) reported B72.3 reactivity in 81% of pulmonary adenocarcinomas and in only 1.7%

of mesotheliomas. Thus, **B72.3 is a useful additional negative marker.**

Surfactant protein B precursor (pro-SB-P)

Thyroid transcription factor-1 (TTF-1)

Latz et al (1990) demonstrated that **BerEP4** was expressed in 99% of adenocarcinomas but in none of 14 mesotheliomas. Subsequent studies reported that a small proportion of mesotheliomas expressed BerEP4, but, in general, the pattern of staining was focal (Ordonez, 1998). **LeuM1 (CD15)** was initially reported as negative in mesotheliomas, but subsequent studies noted that a small proportion of these tumors was positive for this marker (Sheibani et al, 1986). In a study reported by Ordonez (1999), 70% of pulmonary adenocarcinomas were CD15 positive while none of 120 mesotheliomas was positive. **Thus, CD15 appears to be a specific marker for differentiating adenocarcinomas from mesotheliomas but its sensitivity is low.**

MOC31 is a monoclonal antibody prepared against a small cell carcinoma tumor line. Early studies reported by Delahaye et al (1997) showed that MOC31 reactivity was present in 8% of mesotheliomas and 60% of adenocarcinomas. More recent studies have demonstrated MOC31 reactivity in 90% of primary and metastatic carcinomas and in 5% of mesotheliomas (Ordonez, 1999). The monoclonal antibody **BG8** reacts with the blood group antigen Lewis^Y. Early studies reported BG8 reactivity in 100% of pulmonary adenocarcinomas and in 23% of mesotheliomas (Jordon et al, 1989). Subsequent studies by Riera et al (1997) noted BG8 positivity in 93% of pulmonary adenocarcinomas and 9% of mesotheliomas. In the mesotheliomas, staining was most often weak and focal. The Lewis^Y, a blood group antigen, as detected by the **monoclonal antibody CA19-9**, has also been studied in malignant mesotheliomas and adenocarcinomas. In the study reported by Fetsch et al (1998), CA19-9 was present in 3% of mesotheliomas and in 49% of adenocarcinomas.

Khoor et al (1999) have used antibodies to surfactant protein B precursor (pro-SP-B) and thyroid transcription factor-1 (**TTF1**) to distinguish pulmonary adenocarcinomas from mesotheliomas (see Fig. 45-16). Staining for pro-SP-B was present in 50% of adenocarcinomas and 20% of large cell carcinomas while TTF1 was present in 76% of adenocarcinomas and 26% of large cell carcinomas. Both mesotheliomas and squamous cell carcinomas were negative for both markers (Khoor et al, 1999).

Positive Markers

A number of positive markers for mesotheliomas have been developed recently including **thrombomodulin, cytokeratin 5/6, calretinin, N-cadherin, CD44S, HMBE-1, and the Wilms' tumor gene product** (Ordonez, 1999). Initial studies revealed that thrombomodulin was present in 100% of mesotheliomas and 8% of pulmonary adenocarcinomas (Collins et al, 1992). More recent studies, however, have reported that up to 42% of pulmonary

adenocarcinomas may be positive for thrombomodulin. Squamous carcinomas are frequently positive for thrombomodulin and those studies reporting high frequencies of reactivity in adenocarcinomas may have included cases of pulmonary adenosquamous carcinoma. According to Ordonez (1999), up to 80% of mesotheliomas are positive while up to 15% of adenocarcinomas may exhibit positivity.

Moll et al (1989) demonstrated cytokeratin 5/6 in more than 90% of epithelial and biphasic mesotheliomas but in none of 21 adenocarcinomas using the **AE14 monoclonal antibody** in frozen tissue sections. Later, Clover et al (1997) used the **monoclonal antibody, D5/16B4**, in formalin-fixed, paraffin-embedded tissues and demonstrated reactivity in 100% of mesotheliomas and 18.5% of adenocarcinomas. Ordonez (1999) observed positive staining for cytokeratin 5/6 in 100% of mesotheliomas and squamous carcinomas but in none of 30 pulmonary adenocarcinomas. Fifteen percent of nonpulmonary adenocarcinomas were positive for cytokeratin 5/6, but the pattern of staining was generally weak and focal.

Calretinin, a 29kD calcium binding protein, is present in a wide variety of neural and non-neural cells, including steroid-producing cells of the ovary and testis, renal tubular cells, adipocytes, and mesothelioma cells (Andressen et al, 1993). In a large series of cases, Doglioni et al (1996) observed calretinin staining in 100% of mesotheliomas and in 10% of adenocarcinomas (Fig. 45-17). With cytological specimens, Barberis et al (1997) reported positive staining in 100% of mesotheliomas and in 23% of carcinomas. Subsequent studies by Riera et al (1997) reported calretinin positivity in 42% of mesotheliomas and 6% of adenocarcinomas of diverse origins. Variations in the sensitivity of calretinin for the diagnosis of mesothelioma are undoubtedly related to differences in the primary antibodies used. Using the same case material, Ordonez (1999) found calretinin in 100% and 74% of mesotheliomas when 2 different calretinin antibodies were used.

N-cadherin has been found in 92% of mesotheliomas and in 7% of adenocarcinomas while a reverse pattern of reactivity has been found with antibodies to **E-cadherin**. In addition to its presence in mesotheliomas, N-cadherin is also present in serous and endometrioid ovarian carcinomas. However, Simsir et al (1999) have found that neither anti-N-cadherin nor anti-calretinin could reliably distinguish reactive mesothelial cells, malignant mesothelioma cells or adenocarcinoma

P.1662

cells in pleural effusions. These workers also demonstrated that anti E-cadherin is a potentially useful marker in the distinction of adenocarcinoma cells from reactive mesothelial cells but that it was not as useful for the distinction of malignant mesotheliomas and adenocarcinoma. CD44 has also been suggested as a marker to distinguish mesotheliomas from adenocarcinomas. However, Filie et al (1998) have reported CD44 in 90% of mesotheliomas and 43% of adenocarcinomas in cytological preparations. The **monoclonal antibody HBME1**, which was produced against a malignant mesothelioma cell suspension, reacts with an antigen present on the surface of mesothelial cells. The antibody also reacts with cytoplasmic constituents present in adenocarcinoma cells and the distinction between cytoplasmic and plasma membrane staining may at times be difficult to distinguish. Politi et al (2005) incorporated calretinin and HBME into a different panel of antibodies and reported that reactive and malignant mesothelial cells were recognized with very high sensitivity and a specificity of about 75%. The **AMAD2 antiserum**, which directed to a recombinant cytoplasmic mesothelial protein, was positive in 100% of malignant mesotheliomas and 7% of plural metastasis (Donna et al, 1997).

Figure 45-17 Mesothelioma. Core biopsy stained for calretinin shows nuclear and cytoplasmic staining in the tumor cells (see Chap. 26).

Other Markers and Cocktails of Markers

Antibodies to the Wilms' tumor gene protein (WT1) have also been used in immunochemical formats to distinguish mesotheliomas and adenocarcinomas. Amin et al (1995) observed positivity for WT1 in 95% of mesotheliomas, but no positivity was observed in 20 non-small cell lung carcinomas. Kumar-Singh et al (1997) obtained similar results but noted staining in 2 of 2 papillary ovarian tumors and in 1 renal cell carcinoma.

Carella et al (2001) evaluated the efficacy of a set of commercially available antibodies for mesothelioma (calretinin, thrombomodulin, cytokeratins 5/6, and high molecular weight cytokeratins utilizing the monoclonal antibody 34BE12) and for pulmonary adenocarcinoma (MOC31, BerEP4, and polyclonal CEA) with the aid of multiple logistic classification tables. Based on this type of analysis, two **batteries of three antibodies** permitted more than 98% accuracy: (1) BerEP4, CKs 5/6, and calretinin and (2) BerEP4, CKs 5 and 6, and CEA. The authors concluded that these two batteries are equally reliable and that the choice depends on availability of the particular reagents.

Separation of Benign From Malignant Mesothelial Cells

The distinction of reactive mesothelial cells from malignant mesothelioma may also be a formidable problem. Singh et al (1995) have utilized a monoclonal antibody to epithelial membrane antigen (EMA) to aid in this discrimination in cell blocks and cytospin preparations. In their study, EMA immunoreactivity was found in 97% of malignant effusions including all from cases of malignant mesothelioma. Staining for EMA was present in 3.8% of benign effusions. Recent studies indicate that **immunoreactivity for p53** may be helpful in the distinction of benign and malignant effusions. Studies reported by Tiniakos et al (1995) indicated that 43.7% (7/16) of malignant effusions were p53 positive while 2.5% (3/121) of benign and 23.5% (4/17) of suspicious effusions exhibited positivity. Two of three patients whose effusions were classified as benign had subsequent evidence of malignancy while 16 of 17 patients with suspicious diagnoses were subsequently proven to have malignancies. **Estimation of the proliferative fraction using antibodies to MIB1** has also proven helpful in the distinction of benign and malignant effusions. Correlation between MIB1 labeling index (>20%) and effusion type (benign, suspicious or malignant) was statistically significant ($p < 0.0001$) (Saleh et al, 1999). For further comments on identification of mesotheliomas, see Chapter 26.

Liver, Gastrointestinal Tract, and Pancreas

A variety of markers have been utilized for **the distinction of hepatocellular carcinomas (HCCs) from other tumor types**, including cholangiocarcinomas and metastatic adenocarcinomas (Christensen et al, 1989; Johnson et al, 1992). **Alpha-fetoprotein** is a relatively specific marker but its sensitivity is low with positive results in less than 50% of hepatomas. **Alpha-1-antitrypsin (AIAT)** has been reported in up to 80% of HCCs in fine needle aspirates; however, AIAT is **not specific** since it also may be present in gastric, colorectal, pancreatic and renal cell carcinomas (Guindi et al, 1994). Polyclonal antisera and **monoclonal antibodies to CEA** with reactivities directed to biliary glycoprotein typically demonstrate **bile canaliculi** both in normal hepatocytes and hepatocellular carcinomas; however, normal and dysplastic liver cells also demonstrate canalicular staining. In contrast, metastatic adenocarcinomas and cholangiocarcinomas do not exhibit a canalicular staining pattern (Johnson et al, 1992). Wee and Nilsson (1997) demonstrated CEA immunoreactivity in approximately 80% of hepatocellular carcinomas including small cell, clear cell and giant cell variants. However, with increasing anaplasia, the canaliculi become infrequent, irregularly distributed and increasingly distorted and interrupted. The **hepatocytes paraffin monoclonal antibody (HepPar1)** recognizes cells of HCC but also some metastatic tumors (Lugli et al, 2004). **CD 10 (neprilisin)** is expressed in a canalicular pattern in HCCs but not in normal livers. Cells of metastatic carcinomas express diffuse cytoplasmic staining with this reagent. The sensitivity of this stain in the diagnosis of HCCs is 68% and the specificity is 100% (Borscheri et al, 2001).

The **distribution of cytokeratins** has also been studied extensively in these tumors. Johnson et al (1988) demonstrated that 94% of hepatocellular carcinomas were positive for CAM5.2, which reacts with cytokeratins 8 and 18. Only 3% of the tumors were positive with the AE1 monoclonal antibody which is reactive with cytokeratins 10, 14, 15, 16, and 19. In contrast, 100% of cholangiocarcinomas and metastatic tumors involving the liver were positive for CAM 5, 2 and AE1. **Cytokeratins 7 and 20 are absent from most of hepatocellular carcinomas while cholangiocarcinomas typically have a CK7⁺ and CK20⁺ phenotype** (Wang et al, 1995).

Although not specific, **CD34** has been particularly helpful

in the diagnosis of hepatocellular carcinoma (Kong et al, 2001) (Fig. 45-18). This **marker** is present in **endothelial cells** within portal vessels and in a few sinusoidal lining cells adjacent to the portal tracts. In hepatocellular carcinomas, on the other hand, positive staining is present on the surface of the entire lobule and provides an accentuation of the trabecular growth pattern. Regenerative nodules in cirrhotic liver show only slight and focal staining, a pattern which is similar to that of focal nodular hyperplasia.

The **monoclonal antibody MOC31** has been helpful in the distinction of hepatocellular carcinomas from metastatic adenocarcinomas (Niemann et al, 1999). This antibody was generated against a small cell carcinoma line and reacts with a membrane-based glycoprotein of unknown function. **Metastatic carcinomas involving the liver show diffuse cytoplasmic staining while hepatocellular carcinomas are either negative or show only focal positive staining.** Niemann et al (1999) have shown that for metastatic adenocarcinoma, MOC31 positivity has a sensitivity of 83%, a specificity of 87%, a positive predictive value of 83%, and a negative predictive value of 87%. Wang et al (2004) combined MOC31 with HepPar1 to report high specificity and sensitivity in differentiating these two tumor types. A panel consisting of HepPar1, polyclonal CEA, CD 10 and CD 34 is fairly specific in recognition of HCC, with CD 10 staining the bile canaliculi (Fig. 45-18) and CD 34 the capillaries (Saad, 2004). **Antibodies to telomerase** react positively with hepatocellular carcinomas while adjacent nonneoplastic tissue shows focal reactivity in approximately 20% of cases.

Gastric adenocarcinomas may exhibit considerable variability in the expression of CK7 and CK20. Thirty-eight percent of these tumors are CK7⁺/CK20⁺, 35% are CK7⁺/CK20⁻, 17% are CK7⁻/CK20⁻ and 10% are CK7⁻/CK20⁺. Similar to colorectal adenocarcinomas, gastric carcinomas are CEA positive in a high proportion of cases. Other markers that are commonly positive in gastric carcinomas include CA15-3 (100%), BerEP4 (96%) and CA19-9 (92%).

Colorectal adenocarcinomas exhibit a CK7⁻/CK20⁺ phenotype in 75% of cases while 15% of cases are CK7⁺/CK20⁻ and 10% are CK7⁺/CK20⁺ (Wang et al, 1995; Lagendijk et al, 1998) (see Fig. 45-2). The vast majority of mucinous colonic carcinomas are also CK7⁻/CK20⁺. CEA is expressed in most of colorectal adenocarcinomas, although there may be considerable variation in positivity from area to area in any single tumor. **The absence of CEA immunoreactivity in a metastatic adenocarcinoma suggests that the origin is unlikely to be the gastrointestinal tract.** Positive staining for CEA, on the other hand, is not specific for a gastrointestinal primary since a considerable proportion of adenocarcinomas of nongastrointestinal origin will be positive for this marker. Other markers that are commonly positive in colorectal carcinomas include EMA (88%), CA19-9 (83%), B72.3 (78%), and CA15-3 (85%).

Figure 45-18 Hepatocellular carcinoma. A. Diff-Quik stains shows a trabecular growth pattern with transgressing capillaries. B. Immunoperoxidase stain for CD34 in cell block accentuates the vascular pattern.

Pancreatic ductal carcinomas are typically positive with antibodies to broad spectrum cytokeratins. These tumors most commonly **express cytokeratins** of simple epithelial type, including cytokeratins 7, 8, 18, and 19; however, cytokeratins 14, 15/16, and 17 are present in the majority of cases while cytokeratins 5, 10, and 13 are present in a subpopulation of the tumor cells (Real et al, 1993). Approximately 60% of the cases have a CK7⁺/CK20⁺ phenotype while 28% are CK7⁺ and CK20⁻ (Wang et al, 1995). The tumors are positive for EMA (**epithelial membrane antigen**), MUC1, CA15-3, CEA, and BerEP4 in more than 95% of the cases while approximately 80% of the cases exhibit positivity for CA19-9 and B72.3 (Batge et al, 1986; Ichihara et al, 1988; Osako et al, 1993). The antibody DU-PAN2 is positive in more than 80% of pancreatic ductal carcinomas, but the specificity of this reagent is low (Toshkov et al, 1994). Moreover, **ducts in cases of chronic pancreatitis may exhibit positivity for this**

marker and some of the other markers that have been used for ductal tumors.

Molecular approaches have also been used for the diagnosis of these tumors in cytological specimens (van Es et al, 1995).

Acinar cell tumors of the pancreas are also positive for cytokeratins and, in addition, are commonly positive for trypsin and lipase. Positive staining for chymotrypsin and amylase are less common (Klimstra et al, 1992).

P.1664

Pancreatic endocrine tumors are typically positive for cytokeratins and **markers of neuroendocrine differentiation**, including chromogranin and synaptophysin (Saleh et al, 1998). The **hormonal content of these tumors** can also be assessed by the use of antibodies to **insulin, glucagon, somatostatin, pancreatic polypeptide, vasoactive intestinal peptide, and gastrin**. However, the number of cells obtained in most needle aspiration biopsies is usually too limited for full characterization of these tumors. Cell blocks of needle aspirates and core biopsies, on the other hand, often will provide sufficient cellular material (Akosa et al, 1994). Nonfunctional pancreatic endocrine tumors often contain pancreatic polypeptide immunoreactive cells.

Kidney, Urinary Bladder, and Prostate

Renal cell carcinomas commonly coexpress cytokeratins and vimentin (Avery et al, 2000) (see Fig. 45-3). With respect to cytokeratins 7 and 20, approximately 70% of renal cell carcinomas are negative for both cytokeratins and 24% are positive for cytokeratin 7 but negative for cytokeratin 20 (Wang et al, 1995). Renal cell carcinomas are usually positive for EMA and CA15-3. Both **CD10** and **RCC** (a 200 kD glycoprotein expressed in proximal renal tubular cells) are useful reagents for the diagnosis of renal tumors. More than 80% of clear cell carcinoma are positive for RCC and 94% are positive for CD10. **Papillary carcinomas** are also typically positive for both markers. On the other hand, **chromophobe carcinomas** are negative for both markers.

Urinary Bladder and Other Urothelial Tumors

A comprehensive review of immunohistology and immunocytology of the urothelium and urothelial tumors was presented by Nathrath (1995). No specific markers of urothelial cancer were identified among keratins, **although keratin 18 reacted strongly with urothelial carcinoma in situ**. There was little, if any, specificity among blood group-related antigens. Other specific urothelial markers are discussed in Chapter 23. Of special current interest is the application of **antibodies to uroplakins**, specific proteins associated with urothelium is discussed at length in Chapters 23 and 26. In our hands, uroplakin antibodies were reasonably specific as markers of urothelial tumors in dilution 1:10,000. At lower dilutions, nonspecific cytoplasmic staining was observed in a broad variety of cells. Weaver et al (2001) attempted to grade urothelial carcinomas of renal pelvises with antibodies to cytokeratin 20 and CD44 protein with questionable results.

Figure 45-19 Metastatic prostatic carcinoma involving the pelvic bone. *A*. Hematoxylin and eosin stain of cell block. *B*. Immunoperoxidase stain for prostate specific antigen in cell block demonstrates strong cytoplasmic staining.

Prostate carcinomas are typically positive for **broad-spectrum cytokeratins** using the antibodies AE1/AE3 and CAM5.2. The **cytokeratin antibody 34BE12 (K903)** that stains basal cells has also been used extensively for the evaluation of carcinomas in prostatic core needle biopsies. The value of this antibody in prostatic FNA has not been tested. Typically, in histologic sections, **prostatic carcinomas lack basal cells** while benign and hyperplastic glands retain the basal layer (Hedrick and Epstein, 1989). In addition to keratin positivity, prostatic carcinomas frequently express leu 7 (CD57); however, a variety of other tumor types including thyroid carcinomas, synovial sarcomas and carcinoids are also positive (Arber and Weiss, 1995).

Both **prostatic acid phosphatase (PAP)** and **prostate specific antigen (PSA)** are remarkably useful markers for identifying the prostatic origin of metastatic malignancies of unknown origin (Cho and Epstein, 1987) (Fig. 45-19). With the **exception of small cell prostatic carcinomas**, which are often negative for PAP and PSA, most adenocarcinomas of the prostate are positive for one or both markers. Because of the variability in the distribution of these markers, however, variations in positivity due to sampling differences may lead to false-negative results. This is particularly true in the small biopsy samples obtained by fine needle aspiration. **Prostatic acid phosphatase**, however, is not entirely specific for prostatic tumors since immunoreactivity **may also be found in neuroendocrine tumors**, including pancreatic endocrine tumors and carcinoids, particularly those of hindgut origin (Azumi et al, 1991). **Adenocarcinomas of the bladder and breast carcinomas may also demonstrate immunoreactivity for PAP**. However, these tumors are typically negative for PSA. **Prostate specific antigen may be expressed in periurethral glands both**

P.1665

in males and females, in cases of cystitis glandularis and cystica, and in urachal remnants.

Immunoreactivity for PSA also may be present in adenocarcinomas of the bladder, particularly when polyclonal antisera are used (Grignon et al, 1991). Moreover, PSA has also been observed in breast cancers, including those of the male breast, and in certain other tumor types such as those of salivary gland origin (Bodey et al, 1997; Gupta, 1999; Fan et al, 2000).

Prostate specific membrane antigen (PSMA) is a 100 kD cell membrane glycoprotein which is recognized by the monoclonal antibody 7E11-C5. More than 85% of **prostatic carcinomas are PMSA positive as are normal and hyperplastic prostatic tissue**. Epithelial cells of other tumor types are PMSA negative but endothelial cells in renal and urothelial carcinomas, as well as some other carcinomas, are positive. The significance of this finding, however, is unknown (Bostwick et al, 1998; Murphy et al, 1998). Alpha-methylacyl-coA racemase (AMACR) is useful in the detection of prostatic carcinoma but it may also be expressed in other tumor types (Zhou et al, 2002).

Neuroendocrine markers, including **chromogranins and synaptophysin**, may also be found in prostatic adenocarcinomas (Schmid et al, 1994; di Sant'Agneses, 1998). In some studies, the presence of these markers has been associated with decreased survival probability. **Small cell neuroendocrine carcinomas of the prostate** are often positive for chromogranin and synaptophysin.

Female Genital Tract

Cytokeratins are typically present in **ovarian and endometrial carcinomas of all types**.

Mucinous ovarian carcinomas typically exhibit a CK7⁺/CK20⁺ phenotype while **nonmucinous ovarian and endometrial carcinomas are CK7⁺/CK20⁻** (Wang et al, 1995; Filho et al, 1997). A variety of other markers have been utilized for the analysis of tumors of the uterus and ovaries and their distinction from other tumor types. None of the monoclonal antibodies to ovarian carcinomas, however, is specific, but some have shown limited patterns of reactivity. One of the antibodies that has been used most extensively is **OC125, a monoclonal antibody prepared against a human serous ovarian carcinoma** (Bast et al, 1981; Kabawat et al, 1983; Haglund et al, 1986). Immunochemical studies have shown that **CA125 is present on the surfaces of epithelial cells of müllerian origin, mesothelium, amnion, and in carcinomas of the ovary, endometrium, fallopian tubes, and endocervix** (see Fig. 45-6). Comparative studies have revealed that nonmucinous ovarian carcinomas are more commonly OC125 positive than mucinous ovarian carcinomas and carcinomas arising at extra-ovarian and extra-müllerian sites (Bell, 1995). However, positive reactions are also seen in carcinomas of other origins and in mesotheliomas.

Figure 45-20 Papillary serous carcinoma of the endometrium. A. Hematoxylin and eosin stain of cell block. B. Immunoperoxidase stain for p53 in cell block demonstrates strong nuclear staining (see Chapter 14).

Pinto and Kotta (1996) have examined a series of FNAs in female patients in conjunction with assays for CEA and CA125. These studies have demonstrated that increased CEA levels enhance the sensitivity of cytological diagnoses of carcinomas of the colon, pancreas and lung while low CEA and high CA125 levels support an ovarian/endometrial primary.

Legendijk et al (1998) have examined the utility of six antibodies for **the distinction of ovarian and colonic tumors**. The panel included antibodies to CEA, cytokeratins 7 and 20, CA125, vimentin, and CA19.9. This study demonstrated considerable overlap of reactivity for these markers. However, colonic carcinomas were typically positive for CEA and CK20 and negative for CK7 and CA125. Ovarian carcinomas were typically positive for CK7 and CA125 and negative for CEA and CK20. Most ovarian carcinomas, including the mucinous types, could be distinguished from colonic carcinomas with high probability using a **panel of antibodies that includes CEA, CK7, and vimentin**.

Using imprints of surgical biopsies from common epithelial ovarian tumors, Iokim-Liossi et al (1997) demonstrated **no evidence of p53 staining in 15 benign and 3 borderline serous tumors while 74% of malignant tumors were positive** (Fig. 45-20).

Calretinin, a marker extensively used in studies of mesothelioma, is expressed in a wide spectrum of **ovarian sex cord-stromal tumors**, including adult and juvenile **granulosa**

P.1666

cell tumors, fibrothecomas, Leydig cell tumors, Sertoli-Leydig cell tumors, sex cord stromal tumors with annular tubules, gonadoblastomas and sclerosing stromal tumors. McCluggage and Maxwell (2001) demonstrated calretinin immunoreactivity in 97% of sex cord-stromal tumors, the one exception being 1 (of 11) fibrothecomas. In their series, focal reactivity was found in occasional endometrioid carcinomas, endometrial stromal neoplasms, ovarian carcinoids, and Brenner tumors.

Ordenez (1998) has examined the value of a series of markers to **distinguish epithelial peritoneal mesotheliomas from peritoneal and ovarian serous carcinomas**. In this study, calretinin, thrombomodulin and cytokeratin 5/6 were the best positive markers for mesotheliomas. The best diagnostic discriminators among those antibodies typically negative for mesothelioma were MOC31, B72.3, BerEP4, CA19-9 and leu M1. Markers which were not helpful in this differential diagnosis included carcinoembryonic antigen, placental alkaline phosphatase, epithelial membrane antigen vimentin, HBME1, 44-3A6, CA125, and S100 protein. The results of this study also demonstrated that **papillary serous carcinomas of the peritoneum or ovaries could not be distinguished from each other on the basis of these markers**.

The **monoclonal antibody (Mab) 12C3**, which is reportedly specific for human ovarian carcinomas, has also been used in immunochemical formats (Yamada et al, 1995). **This antibody reacted with the majority of carcinomas but was negative in benign tumors**. Cases of borderline tumors showed positive reactions in regions of cellular atypia. These data suggest that Mab 12C3 could be useful in the detection of early malignant change in epithelial ovarian tumors. The p53 mutation has been shown to be an important marker in the identification of **intraepithelial carcinoma of the endometrium** (see Chap. 13).

Figure 45-21 Metastatic thyroid follicular carcinoma involving the scalp. *A*. Diff-Quik stain of ThinPrep. *B*. Immunoperoxidase stain for thyroglobulin in ThinPrep demonstrates strong cytoplasmic staining. *C*. Histological section of resected metastatic thyroid carcinoma.

In reference to the **uterine cervix**, many efforts have been made in recent years to find specific morphologic markers for identification of neoplastic cells in cytologic preparations, thus facilitating the screening process. Most of these efforts failed. More recently, an **antibody to p16^{INK4A}**, a tumor-suppressor protein, was proposed as a marker for high grade squamous and endocervical neoplastic lesions (Klaes et al, 2001; Negri et al, 2003; Bose et al, 2005). The antibody is not expressed in normal epithelium and its presence depends on the E7 open reading frame of high risk human papillomaviruses (see Chap. 11). The acceptance of this approach to cervix cancer detection is uncertain.

Endocrine Glands

Thyroid and Parathyroid

Thyroglobulin is a remarkably useful marker for papillary and follicular neoplasms of the thyroid (see Diagram 45-3). Virtually all follicular adenomas and well-differentiated follicular carcinomas, and more than 90% of papillary carcinomas, are thyroglobulin positive (Bocker et al, 1981; Tung et al, 1995; Bejarano et al, 2000) (Fig. 45-21). In

P.1667

both tumor types, however, there is often considerable **heterogeneity in the distribution of thyroglobulin** such that small biopsies may be negative. **Poorly differentiated carcinomas** originating from well-differentiated papillary or follicular neoplasms are less frequently positive while **undifferentiated carcinomas** are usually thyroglobulin negative (Carcangiu et al, 1984; Ordonez et al, 1991).

Thyroid carcinomas of all types **are positive for cytokeratins and a substantial proportion coexpress vimentin** (Fig. 45-22). Most of these tumors exhibit a CK7⁺/CK20⁻ phenotype (Bejarano et al, 2000). Papillary carcinomas are usually reactive with high molecular weight cytokeratins and also with antibodies to CK19 (Miettinen et al, 1997; Baloch et al, 1999; Kragsterman et al, 1999; Liberman and Weidner, 2000; Sahoo et al, 2001). Most studies have demonstrated strong and **diffuse staining for CK19 in papillary carcinomas and weak or absent staining in follicular neoplasms and hyperplastic nodules** (Raphael et al, 1994, 1995; Schelfhout et al, 1989). Cytokeratins 5/6 and 13 were present in a high proportion of papillary carcinomas, in contrast to their absence from normal thyroid and follicular neoplasms (Fonseca et al, 1997). However, the number of CK 5/6 and 13 positive cells in papillary tumors was generally low. **Involucrin** is present in approximately 70% of papillary carcinomas and 30% of follicular tumors (Liberman and Weidner, 2000).

Thyroid transcription factor-1 is present in more than 95% of papillary carcinomas and follicular neoplasms while only 20% of Hürthle cell (oncocytic) neoplasms are positive (Ordonez, 2000). Insular or poorly differentiated carcinomas are typically positive while anaplastic carcinomas are typically negative (Bejarano et al, 2000).

A variety of other markers including CA15-3, CA19-9, CA125, lactoferrin, leu 7 (CD57), HBME1, and CD15, have been studied in the thyroid gland with respect to their **potential in distinguishing benign and malignant lesions**. CA15-3 is present in 100% of papillary carcinomas while CA19-9 has been reported in 70% of papillary carcinomas but in no cases of follicular carcinoma (Gatalica and Miettinen, 1994). CA125 has been reported in approximately 40% of papillary carcinomas (Keen et al, 1999). Asato de Camargo et al (1996) have proposed **that lactoferrin is useful in the distinction of malignant from benign lesions in cytological smears**. In tissue sections, leu 7 (CD57) has been reported to be strongly expressed in follicular and papillary carcinomas (Ghali et al, 1992); however, studies of cytological specimens have demonstrated reactivity both in benign and malignant lesions (Ostrowski et al, 1995). **HBME1** has also been utilized to distinguish benign and malignant thyroid lesions. In aspirated material, HBME1 was present in 5 of 7 (72%) of papillary carcinomas, 1 of 1 follicular carcinoma and 1 of 1 anaplastic carcinoma (Sack et al, 1997). In contrast, there was no staining of 5 follicular adenomas/hyperplastic nodules, 3 Hürthle cell adenomas, 1 nodular goiter, and 1 case of chronic thyroiditis. In histologic sections, 100% of carcinomas were positive while 3 of 5 adenomas exhibited some reactivity. In benign lesions, the staining was weak and focal. These findings suggest that **positive staining for HBME1 can be a valuable adjunct in the cytological diagnosis of malignancy**; however, a positive result does not guarantee that the lesion is malignant. CD15 is present in approximately 30% of papillary carcinomas and the studies of Schroder et al (1987) indicate that the presence of this marker is more likely to occur at advanced stages of the tumor.

Figure 45-22 Anaplastic thyroid carcinoma. A. Diff-Quik stain of ThinPrep. B. Immunoperoxidase stain for cytokeratins (AE1/AE3) demonstrates faint cytoplasmic positivity in ThinPrep.

An **antibody panel consisting of HBME1, CA19-9 and CD15** has been used as an adjunct to the diagnosis of papillary carcinoma of the thyroid. These studies have demonstrated that HBME1 is a sensitive marker of papillary carcinoma; however, CD15 and CA19-9 are less sensitive but more specific (van Hoesen et al, 1998). CD44 has been studied in cytological samples as a marker for papillary carcinoma (Ross et al, 1996). Chhieng et al (1997) have demonstrated **that CD44 is expressed in a membranous pattern in papillary carcinomas** while nonpapillary carcinomas and benign lesions are often negative. **Galectin-3** has been shown not to be useful in the diagnosis of thyroid carcinoma (Mehrotra et al, 2004).

Steroid receptors are variably expressed in thyroid tumors. Bur and associates (1993) have demonstrated **estrogen receptor** positivity in 21% of papillary carcinomas but follicular and Hürthle cell tumors were negative. **Progesterone receptor** was present in 33% of papillary carcinomas, 40% of

P.1668

follicular tumors (adenomas and carcinomas), and 53% of Hürthle cell tumors. There was no significant association between steroid hormone positivity and age, gender, or clinical course.

The **ret oncogene protein** has been demonstrated by immunochemistry, both in papillary carcinomas and in a subset of hyalinizing trabecular adenomas (Tallini et al, 1998; Papotti et al, 2000). In a comparative study of cytokeratin 19, ret and HBME1, Cheung et al (2001) demonstrated that all cases of nodular hyperplasia and follicular adenoma were negative for HBME1 and ret, but some of these cases exhibited focal CK19 immunoreactivity, particularly in areas of degenerative change. Approximately 50% of follicular and anaplastic carcinomas were HBME1 positive but none was positive for ret or CK19. Overall, 20% of the papillary carcinomas were positive for all three markers. Papillary carcinomas of the classic type were positive for ret (78%), HBME1 (70%), and CK19 (80%). Cases of the follicular variant of papillary carcinomas were positive for HBME1 in 45% of cases, for CK19 in 57% and ret 63%. Insular carcinomas were positive for HBME1 (67%), ret (50%), and CK19 (50%). Hürthle cell carcinomas were positive for HBME1 (29%), CK19 (29%), and ret (57%).

Medullary carcinomas are positive for cytokeratins and most often exhibit reactivity for **calcitonin, chromogranin and other markers of neuroendocrine differentiation** (De-Lellis and Wolfe, 1981; Collins et al, 1995) (Fig. 45-23). These tumors may also contain a variety of other peptides, including **somatostatin-** and **gastrin-releasing peptides**. **CEA is typically strongly expressed in medullary carcinomas** and this marker is often positive in those tumors that have lost the ability to produce calcitonin (Dasovic-Knezevic et al, 1989). Almost 90% of medullary carcinomas are TTF1 positive (Bejarano et al, 2000). The rare examples of mixed C cell and follicular/papillary carcinomas stain positively for calcitonin and thyroglobulin (Holm et al, 1986; Volante et al, 1999).

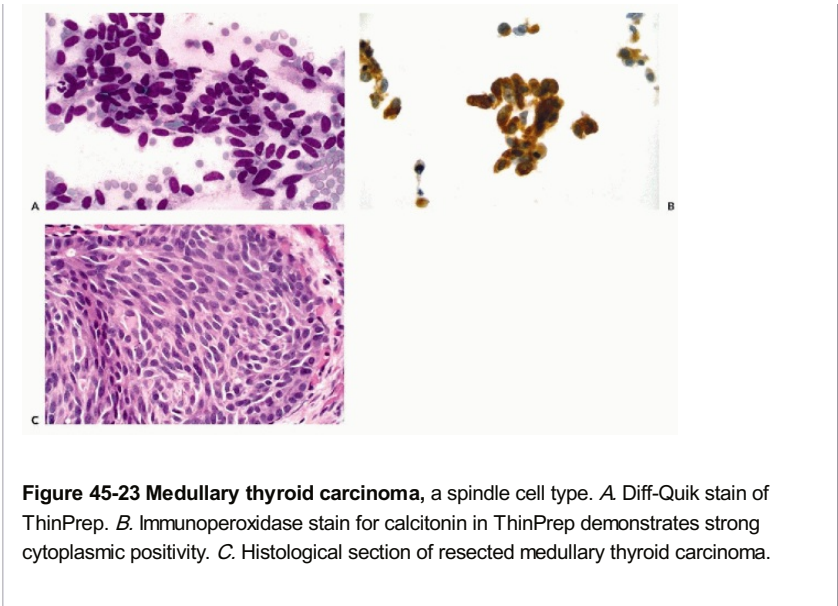

Figure 45-23 Medullary thyroid carcinoma, a spindle cell type. A. Diff-Quik stain of ThinPrep. B. Immunoperoxidase stain for calcitonin in ThinPrep demonstrates strong cytoplasmic positivity. C. Histological section of resected medullary thyroid carcinoma.

Normal and neoplastic parathyroid tissue is typically positive for chromogranin and parathyroid hormone (PTH) in contrast to thyroid follicular cells which are negative for both of these markers. Normal C cells and medullary thyroid carcinomas are positive for chromogranin but also exhibit positivity for calcitonin and the calcitonin gene-related peptide.

Adrenal Glands

Tumors of the **adrenal cortex** most commonly have a **vimentin positive and cytokeratin negative phenotype** (Table 45-6) (Gaffey et al, 1992). However, some cortical tumors may be positive for cytokeratins, particularly following antigen retrieval. Cortical neoplasms may also be identified on the basis of **expression of enzymes involved in steroidogenesis**, but antibodies to these enzymes are not generally available. The monoclonal **antibody D11** recognizes several 59 kD proteins that are capable of binding

P.1669

apolipoprotein E. Reactivity for D11 has a nuclear distribution in adrenal cortical cells; however, the antibody also stains the cytoplasm of a variety of other tumor types (Schroeder et al, 1990; Tartour et al, 1993). **The nuclear adrenal 4 binding protein (Ad4BP)** is a transcription factor that regulates steroidogenic cytochrome P450 gene expression. Antibodies to Ad4BP typically produce nuclear staining. Adrenal cortical tumors are typically **positive for Ad4BP** while other tumor types are negative (Sasano et al, 1995).

The **monoclonal antibody A103, which reacts with the melanocyte specific antigen, Melan A, is a particularly useful marker for the identification of steroid-producing cells** (Chen et al, 1996; Busam et al, 1998; Jungbluth et al, 1998) (Fig. 45-24A). The immunoreactive moiety recognized by A103 in adrenal cortical and other steroid-producing cells is most likely due to a cross-reacting antigen that is genetically different than Melan A. **The A103 antibody is particularly useful to distinguish normal adrenal cortex and cortical neoplasms from metastatic carcinomas in fine needle samples** (Shin et al, 2000) (Fig. 45-24B). **Antibodies to inhibin A are also useful for the identification of adrenal cortical cells.** Renshaw and Granter (1998) have compared the reactivities of A103 and inhibin A in a series of adrenal cortical neoplasms, renal cell tumors and hepatocellular carcinomas. They concluded that A103 was marginally more specific and that inhibin A was slightly more sensitive for the identification of cortical cells. Calretinin is also commonly expressed in cortical tumors (Zhang et al, 2003).

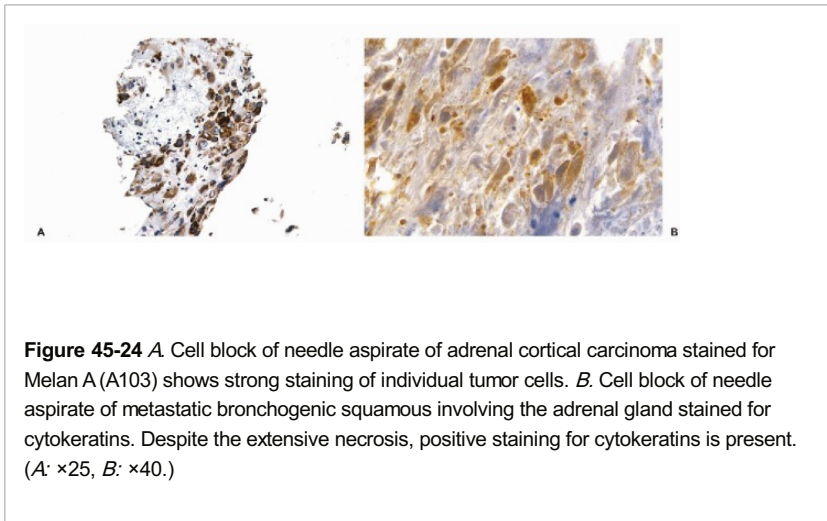

Figure 45-24 A. Cell block of needle aspirate of adrenal cortical carcinoma stained for Melan A (A103) shows strong staining of individual tumor cells. B. Cell block of needle aspirate of metastatic bronchogenic squamous involving the adrenal gland stained for cytokeratins. Despite the extensive necrosis, positive staining for cytokeratins is present. (A: $\times 25$, B: $\times 40$.)

Occasional **cortical tumors may show evidence of neuroendocrine differentiation**, as manifested by positive staining for neurofilament proteins, neuron specific enolase and synaptophysin (Komminoth et al, 1995). Chromogranin immunoreactivity, however, is typically absent.

Tumors of the adrenal medulla, including pheochromocytomas and neuroblastomas, contain neurofilaments and vimentin as their major intermediate filaments. The most **useful markers** for neoplastic medullary cells include **chromogranins, neuron specific enolase and synaptophysin**, as discussed in a previous section. It should be remembered, however, that neuron specific enolase and synaptophysin may be present in neoplastic cortical cells as well. Antibodies to **catecholamine-synthesizing enzymes** may also be of value in selected cases. The **sustentacular cells of pheochromocytomas can be demonstrated selectively with antibodies to S100 protein.**

PROGNOSTIC MARKERS

Although the emphasis in this chapter has been on the utilization of antibodies for specific diagnostic purposes, there are also applications of this technology for prognostic assessment of different tumor types. For example, current **immunotherapy**

P.1670

regimens utilizing gp-100 (HMB45) and the melanoma antigen recognized by T cells (MART) depend on the presence of these antigens in fine needle aspirates of metastatic lesions (Abati et al, 1998). Cormier et al (1998) reported a case in which a patient with melanoma experienced rapid tumor progression in association with loss of either melanoma-associated antigens or HLA expression.

Assessment of proliferative activity also provides important prognostic information and has been used in some instances to differentiate low-grade and high-grade carcinomas of the breast and a variety of other sites (Cohen et al, 1993; Pelosi et al, 1994; Boon et al, 1996; Bozzetti et al, 1997; Saleh et al, 1999). **Proliferation markers** that have been used most extensively in immunochemical formats include the **proliferating cell nuclear antigen (PCNA)** and **Ki-67**. **PCNA** is an auxiliary protein of DNA polymerase delta. **Immunoreactive PCNA increases in late G₁, peaks in the S-phase and decreases through the G₂ phase,**

reaching undetectable levels in the M-phase and in G₀. **The MIB1 antibody** is raised to a recombinant portion of Ki-67, a human nuclear antigen, present in cycling but not resting cells. Most recent studies of proliferative activity have utilized the MIB1 monoclonal antibody which produces distinct nuclear immunoreactivity. In the protocol reported by Suthipintawong et al (1997), freshly made smears were air dried for 20 minutes to 14 hours at 22°C before fixation in buffered formalin for 2 to 14 hours. Immunostains were performed after microwave antigen retrieval. In general, there was an excellent correlation between the results obtained with smears and tissue sections.

p27 (kinase inhibitor protein [kip] 1) is a cyclin-dependent kinase inhibitor which blocks the cell cycle by binding the cyclin ECdk2 complex. Many normal tissues and benign tumors have nuclear levels of p27 which can be visualized in immunochemical formats while **reduced expression of p27 in tumors has been correlated with a poor clinical outcome**. In a study of **mesotheliomas**, Beer et al (2001) reported that tumors with low p27 expression (<53% positive cells) had a worse prognosis than those with high p27 expression (>53% positive cells). **Apoptotic cells** have also been detected effectively in cytological preparations **utilizing TdT-mediated deoxyuridine triphosphate (dUTP)-biotin nick end labeling (TUNEL reaction)** (Sasano et al, 1998). Smears that were fixed with 4% or 8% paraformaldehyde or absolute methanol gave results that were comparable to those obtained in tissue sections while cells fixed in Carnoy's fluid or air dried gave higher background. Another approach for the identification of apoptotic cells involves the use of **annexin V** which binds in a calcium dependent manner to exposed phosphatidylserine (Barrett et al, 2001). The use of this method is based on the fact that when cells undergo apoptosis, phosphatidylserine (normally sequestered on the cytoplasmic face of the plasma membrane) appears on the exterior of the cell where it can bind to labeled annexin V. However, only a minority of apoptotic cells label with annexin V before the final lysis of cells at the end of apoptosis. Of greater promise is the use of assays for **caspase substrate cleavage products** and, in particular, the demonstration of **cleaved cytokeratin 18**. Although this approach has been used successfully in cell culture, preliminary results indicate that it may be useful in archival, paraffin-embedded samples (Barrett et al, 2001). This issue is discussed at length in Chapter 47.

Steroid receptors, including those for estrogen (ER), progesterone (PR), and androgen (AR), represent another important class of prognostic markers (see Figs. 45-14 and 45-15). The results of a number of studies have demonstrated that the immunochemical approach for the demonstration of ER and PR is highly sensitive and specific. Moreover, additional studies have demonstrated **an excellent correlation between traditional dextran charcoal-based methods and immunochemistry**. Immunocytochemical methods for ER and PR are readily adaptable to cytological materials including fine needle aspirates, touch imprints, malignant effusions, cytopins, and ThinPreps (Masood, 1992, 1994; Hudock et al, 1996; Abati et al, 1998; Tabbara et al, 1998). Suthipintawong et al (1997) have found that air dried smears, fixed in 10% buffered formalin and subsequently subjected to microwave induced antigen retrieval, provide reproducible conditions for the demonstration of ER and PR. Tabbara et al (1998) have demonstrated that estrogen and progesterone receptor are preserved both in stored ThinPreps and newly prepared ThinPreps of mammary tumor cells over a 56-day storage period. The ability to perform ER and PR in cytological preparations is particularly valuable for patient management issues, including patients who require preoperative chemotherapy, in cases of recurrent or metastatic breast cancer, and in cases in which breast cancer is considered in the differential diagnosis.

A variety of oncogene and tumor suppressor gene products have been demonstrated in cytological preparations. **Her2/neu is a proto-oncogene** which encodes a 158-kD transmembrane protein that shares homology with epidermal growth factor (see Fig. 45-14). Overexpression of Her2/neu in breast cancer is associated with a poorer prognosis than tumors which are Her2/neu negative. The presence of Her2/neu is also used to determine whether patients qualify for treatment with a **monoclonal antibody to Her2/neu (Herceptin)**. Her2/neu has been demonstrated in a variety of cytologic preparations and in slides previously stained by the Papanicolaou procedure with excellent correlation of the staining results with those obtained in formalin-fixed, paraffin-embedded materials (Corkill and Katz, 1994; Martin and Davey, 1996; Suthipintawong et al, 1997; Troncone et al, 1996). **The reaction of Her2/neu is considered positive when the stain is present in a rim-like pattern corresponding to the plasma membrane. Cytoplasmic staining alone is considered negative**. Air-dried smears, subsequently fixed in 10% buffered formalin, also provide good results (Suthipintawong et al, 1997).

p53 is a tumor suppressor gene located in the short arm of chromosome 17. Numerous studies have demonstrated that p53 is the most frequently mutated gene in human cancer (see Chap. 3). The wild type of the p53 protein has a very short half life and is generally not demonstrable immunochemically. The mutated form of the p53 protein, on the other hand, is stabilized in tumor cells and

can be demonstrated both in histological and cytological preparations (see Fig. 45-20).

Staining for p53 is considered positive when immunoreactivity is present within the nucleus. Immunohistochemical staining for p53 has been performed on a variety of cytological preparations, including cell blocks, direct smears and fine needle aspirates (Bartek et al, 1991; Connelly et al, 1992; Bruner et al, 1993; Pelosi et al, 1994; Colecchia et al, 1995; Alexiev et al, 1996; Ioachim-Liossi et al, 1997, 1998; Lee et al, 1997; Athanassiadou et al, 1998; Saleh et al, 1998; Sato et al, 1998). In general, the result obtained in histological materials provided similar results to those obtained in cytological samples (Colecchia et al, 1995; Ioachim-Liossi et al, 1998). **p53 immunostaining of effusions** (see Chap. 26) has been demonstrated to be of value in identifying carcinoma cells, particularly in those areas with inconclusive or bland cytological features (Saleh et al, 1998).

NUCLEOLAR ORGANIZER REGIONS (NORs)

Although not representing an immunochemical method, techniques for the analysis of nucleolar organizer regions (NORs) are an important adjunctive cytological technique. The number of AgNORs generally correlates with proliferative activity (see Chap. 7). The NORs, which are **loops composed of nonhistone proteins and DNA, have an affinity for colloidal silver (Ag)**. NORs in tissue sections and imprint preparations appear as black dots; however, enumeration of AgNORs is difficult, and generally all silver positive dots, both within and outside the nucleoli, are counted using an oil immersion lens. Numerous studies have been published regarding the value of AgNORs as an adjunct to tumor grading and prognostic assessment. Malignant cells often demonstrate dispersed AgNORs throughout the nucleus and in association with multiple nucleoli which contain clustered AgNORs. Benign cells tend to have a regular nucleolus with tightly clustered Ag-NORs.

Studies of AgNORs in paraffin-embedded sections show discrepancies due to the difficulty of counting AgNORs in sectioned material, at least in part related to variations in tissue fixation and section thickness. This technique has also been applied to cytologic preparations which are considerably easier to quantitate (Crocker and Paramjit, 1987; Crocker et al, 1989; Cardillo, 1992; Sujathan et al, 1996; Chern et al, 1997; Mahovic et al, 1999). **In comparative studies of paraffin-embedded and imprint preparations of bladder cancer, the mean AgNOR count was higher in imprints and showed a much better correlation with nuclear grade.** Imprints have also been used for the evaluation of AgNORs in lymphomas and breast carcinomas.

MOLECULAR APPROACHES

The principles of the molecular biologic techniques are discussed in Chapter 3. Molecular technologies are being used with increasing frequency in many areas of diagnostic cytopathology and in an ever-expanding series of research applications utilizing cytological samples. To date, many of these applications have been focused on human papillomavirus (see Chap. 11). Additional applications utilize polymerase chain reaction (PCR)-based detection of clonality in hematological and non-hematological malignancies, PCR based **detection of translocations and rearrangements in solid tumors**, detection of single base mutations or polymorphisms and assays for loss of heterozygosity of tumor suppressor genes (Rimm, 2000). For example, Cheung et al (2001) have successfully utilized thyroid aspirates collected in Cytolyt for a reverse transcriptase (RT) PCR study of ret/PTC rearrangements. The results of this study demonstrate **that RT-PCR for ret/PTC is a specific marker for papillary thyroid carcinoma** and that this approach can be applied successfully to aspirated samples.

In situ hybridization techniques combine molecular and histochemical approaches and offer a powerful method for the detection and localization of DNA and RNA at the cellular level (DeLellis and Wolfe, 1991; Hofler et al, 1993; Jin et al, 2001). These methods are derived from Southern and Northern blotting procedures and are complementary to these techniques (see Chap. 4). In contrast to immunocytochemistry which is dependent on the reaction of antibody and antigen, **in situ hybridization analyses offer the possibility of identifying cells on the basis of a specific hybridization reaction with a labeled probe and its complementary intracellular target DNA or RNA.** These technologies are particularly useful for the identification of specific chromosomal abnormalities and for localization of foreign DNA and RNA from viruses and other organisms. The major advantage of **in situ** hybridization approach is its specificity in identifying individual abnormal cells in a mixed cell population and its sensitivity for detection of low copy gene expression in single cells and chromosomes (Jin et al, 2001).

Both unfixed and fixed tissues and cell preparations have been used successfully for **in situ** hybridization studies. **Four percent paraformaldehyde has been considered the fixative of choice.** Pretreatment of preparations with proteases is essential to permit access of the

probe with the target nucleic acid (Jin et al, 2001). Cytocentrifuged specimens, as well as other types of cytological preparations, including direct smears, have also been used for **in situ** hybridization analyses (DeLellis and Wolfe, 1991).

Numerous probes have been developed for these analyses. These include nick-translated, double stranded or randomly primed DNA, synthetic single stranded oligonucleotides (30-50 bases), and single stranded printed antisense (complementary) RNA probes. The choice of a particular probe depends on multiple factors including sensitivity and specificity, ease of penetration and stability of the resultant hybrids. For the analysis of **messenger RNA, cRNA probes** offer a number of advantages, including high hybridization efficiencies, constant probe size, lack of back hybridization, and the ability to reduce background by treatment of sections with RNase in order to remove nonhybridized single stranded RNA. Moreover, RNA-RNA hybrids are more stable than DNA-DNA or DNA-RNA hybrids.

P.1672

A recent important application of this technology in diagnostic cytology is the development of an **in situ** hybridization kit for detection of high risk human papillomavirus in cervical preparations (**Inform HPV, Ventana Medical Systems, Tucson, AZ**). Conceptually, similar to the **Hybrid Capture 2 (HC2)** system, which is described and illustrated in Chapter 11, the Inform HPV Family 16 cocktails cover virus types 16, 18, 31, 33, 35, 39, 51, 52, 56, 58, and 66 (Hesselink et al, 2004; Castle et al, 2004). The Inform HPV has not received widespread use as of the time of this writing.

In the past, probes have been labeled primarily with **radioactive markers**, such as ^3H , S^{35} , ^{125}I , and ^{32}P . Although tritium (^3H) produces the highest degree of resolution, exposure times are quite long, thereby limiting usefulness of these probes for clinical samples. More recently, **nonradioactive probes labeled with biotin, digoxigenin, fluorescein, enzymes or bromodeoxyuridine have begun to replace radioactive probes for clinical samples.** An additional approach for signal detection includes the use of **catalyzed reporter deposition (CARD)** utilizing labeled tyramide for signal amplification (Frater and Tubbs, 2001).

The results of **in situ** hybridization can be influenced by a large number of variables which must be vigorously controlled if reliable and reproducible results are to be obtained. As a rule, correlative molecular studies should be performed in order to validate results. Protocols, combining **in situ** hybridization with the polymerase chain reaction, have also been developed by many investigators, but these approaches must be rigorously controlled to avoid false positive reactions (Komminoth et al, 1992; Hofler, 1993; Nuovo, 1997).

Fluorescence in situ hybridization (FISH) is a powerful technology which permits the localization of a particular DNA sequence to a specific chromosome or chromosomal region (Kontogeorgos et al, 2001; Sheldon, 2001). FISH depends on the formation of a **hybrid between a fluorescently-labeled DNA probe and its target chromosomal DNA.** The methodology involves denaturation of the probe and target sequences, reannealing of the probe and target and visualization of the resultant hybrid by fluorescence microscopy (see Chap. 4). Posthybridization washes of high stringency result in the removal of any unbound probe. Formalin can be used for fixation, but the best results are generally obtained with methanol/glacial acetic acid (Carnoy's solution) or acetone. The specific methodological details are discussed elsewhere.

Applications of this technique include gene mapping and the demonstration of gene amplifications, deletions, translocations and numerical chromosomal aberrations (Wolman, 1997). Alpha-satellite centromeric, beta-satellite centromeric, and classical satellite probes, specific for tandem repeats of DNA sequences of individual chromosomes, are particularly useful for the detection of copy number aberrations in interphase nuclei. **Painting probes provide sequences that can identify entire chromosomes** (see Chap. 2). Such probes are of particular value for identifying chromosomes that carry complex translocations not involving the centromere. They are also of value for the analysis of translocations for which a specific probe is not yet available. Sequence specific cosmid probes are of value for the detection of marker chromosomes, other structural aberrations, translocations and complex rearrangements and are also used for the demonstration of amplifications and deletions.

The relatively easy to perform technique of FISH has found several applications in diagnostic cytology. The initial application was the diagnosis of **cancer in urinary sediment** (Sokolova et al, 2000; Veeramachanemi et al, 2003). The system UroVysion (Vysis, Downers Grove, IL) is described and illustrated in Chapter 23. Numerous reports of **FISH application to effusions** are summarized in Chapters 25 and 26. **In situ** hybridization kit LAVysion (Vysis, Downers Grove, IL) for the diagnosis of **bronchogenic carcinoma** has also been tested with interesting results (Sokolova, 2002). This kit, supplemented by two in-house produced additional probes, has been reported as a possible tool of lung cancer detection (Barkan et al, 2005).

Comparative genomic hybridization (CGH) is a modified **in situ** hybridization technique

which permits the detection and mapping of DNA sequence copy differences (gains and losses) in a single assay (Kallioniemi et al, 1992). **Genomic DNA derived from normal lymphocytes and tumor, differentially labeled with different fluorochromes** (fluorescein isothiocyanate and Texas red) and Cot-1 DNA (to suppress cross hybridization of repetitive sequences), are denatured and hybridized to denatured metaphase spreads of normal lymphocytes. Following posthybridization washes, digitized three color images prepared from hybridized metaphase spreads, are processed with an image analyzer designed for karyotypic analysis. The system, which is based on analysis of the **fluorescence intensity ratio between red and green signals** and comparison with that of simultaneously hybridized normal DNA in the same spreads, automatically reports gains and losses (Lichter et al, 2000; Tachdjian et al, 2000). The display generates ideograms with vertical bars indicating losses and gains of the corresponding chromosomal regions for each chromosome (see Chap. 4). **CGH can be combined with DNA microarrays in a procedure known as matrix CGH.**

Microarray technology has emerged recently as a high throughput approach for analysis of genes and patterns of gene expression. Tissue microarrays are assembled by taking core samples from pre-existing paraffin blocks and reembedding them in an arrayed master block, as described originally by Kononen et al (1998). Hundreds of samples can then be analyzed by immunochemistry or **in situ** hybridization. With the Beecher instrument, each sample is 0.6 mm in diameter and up to 600 samples can be arrayed on a single slide (Fig. 45-25). A potential limitation of this approach is the relatively small tissue volume represented in each core. In order to validate the use of this approach for immunophenotyping, Hoos et al (2001) studied a group of 59 fibroblastic tumors by immunochemistry for Ki-67, p53, and the retinoblastoma protein (pRB) and demonstrated that **triplicate cores** provide a higher rate of assessable cases and a lower rate of nonconcordant readings than one or two cores. Concordance between full sections and triplicate cores was high (96%-98%) for two category distinctions

P.1673

(positive or negative for Ki-67 and p53) and decreased to 91% for three category distinctions (high, moderate, or negative for pRB). **Tissue microarrays** provide a number of advantages when used in **immunochemical formats**. Firstly, a small amount of antibody can be used for the analysis of hundreds of samples. Secondly, minor variations in antigen retrieval can be essentially eliminated because all samples will be exposed to exactly the same retrieval conditions. Finally, slight variations in antibody concentrations, incubation times and washing steps will be essentially identical for all samples. To date, there are relatively few applications in **cytopathology**; however, this approach holds a great deal of promise for the analysis of **patterns of protein expression in effusions** and other types of cytological specimens (Rimm, 2001).

Figure 45-25 Tissue microarray for colorectal carcinoma. From each specimen (i.e., regular tissue block), triplicate tissue cores with a diameter of 0.6 mm were punched and arrayed on a recipient block (the array block). Normal tissue blocks were also used to construct the array block. Five microns sections from the array block were cut and used for H&E and immunostaining for p53. *Left:* Overview of the array H&E section. *Right:* View of the H&E and p53 stainings of two tissue cores present in the array. Up to 500 tissue cores can be placed on an array without hampering the quality of the array section. (Courtesy of Dr. Axel Hoos, Antigenics Inc, New York, NY.)

DNA microarrays are matrices of thousands of cDNAs or oligonucleotides imprinted on a solid support system (Alizadeh et al, 2000; Kurella et al, 2001; Okabe et al, 2001; Shirota et al, 2001; Watson et al, 2001). Basically, **labeled mRNA from the cells of interest are hybridized to their corresponding sequence on the array** to provide a measure of mRNA abundance in the sample. The result of this type of analysis is the expression profile or pattern of gene

expression characteristic of the unknown sample. Arrays can now be miniaturized so that hundreds of thousands of oligonucleotides can be arrayed on a square centimeter chip. This approach is now being used for the characterization of gene expression patterns in a wide variety of different tumor types. Data derived from these types of study will undoubtedly lead to new systems of tumor classification and therapy based on characteristic molecular fingerprints (Hedenfalk, 2001).

Digital Analysis of Cells and Tissues

Peter H. Bartels
Deborah Thompson
Leopold G. Koss

Digital microscopy provides a numeric representation of diagnostic imagery that offers some distinct advantages over conventional visual microscopy. Digital data establish a **permanent reproducible record** that can readily be distributed, archived, communicated and displayed at variable magnifications. They are ideally suited for teleconsultation and, as virtual slides, for teaching. The numeric representation also provides the basis for **quantitative analysis** of diagnostic images. Quantification introduces a wealth of novel information and concepts.

How does all of this relate to established diagnostic practice? Knowledge in diagnostic cyto- and histopathology is communicated in linguistic terms and concepts. Although these terms are fuzzy, they theoretically carry an extraordinary amount of highly specific information. Quantification of diagnostic images is not meant to replace visual images or create new diagnostic concepts. Rather, the challenge is to **express well-proven diagnostic clues and concepts in numeric terms**. It has become clear, however, that quantification generates a body of “digital knowledge” that is uniquely derived from computer processing of digitally represented images in cytopathology and histopathology. Developments in information science have allowed an objective, quantitative evaluation of these images, which can be expressed in understandable linguistic terms and are based on an accumulation of multiple diagnostic clues. These methods have led to the development of automated or semiautomated diagnostic decision support systems, and to objective standards for diagnosis defined by digital imagery. Table 46-1 lists the principal targets of applications of image analysis techniques. Many, but not all, of these targets are discussed in this chapter which is dedicated to the description of the methods and their principal applications based on simple instrumentation.

THE DIGITIZED IMAGE

The microscopic image is formed as a distribution of brightness and darkness in an “image plane.” It is a continuous distribution. In video-photometry, this image is projected onto the faceplate of a video camera, typically a **charge-coupled device (CCD)** array. The CCD samples the image by its array of sensor elements and the image is now represented

P.1682

by an array of discrete points or **picture elements called pixels**.

Analysis of DNA and RNA microarrays

The light energy sensed at each point is recorded in digital form and stored in computer memory.

It is essential to project the microscopic image onto the CCD at an adequate magnification. The finest detail that the original image can offer is restricted by features of the objective, such as the numerical aperture. The magnification at the faceplate of the CCD should be chosen to maintain "useful magnification," i.e., to preserve the objective's resolving power by the CCD

elements. In practice, one would oversample, i.e., have two or more CCD elements covering an image region corresponding to the point spread function of the objective.

Figure 46-1A shows a digitized image of a human embryonic lung cell, recorded in 1966 at the University of Chicago in the study that initiated the **taxonomic intracellular analysis system (TICAS)** project (Wied et al, 1968). The numbers are "pixel optical density values." Today's digitized images are sampled at a spacing approximately 40 × closer, yielding several thousand pixels per nucleus (Fig. 46-1B). Images are recorded in the form of "light intensity values," ranging from 0 to 255, with 0 denoting total darkness and 255 full 100% transmission. It is customary to convert the light intensity value image to pixel optical density (OD) values. These range from optical density OD = 0, denoting full brightness, to OD = 3.00, indicating a light transmission of 1 per 1,000, i.e., very dark. In practice, one multiplies these values by 100 in order to store them in memory as integer form. A pixel OD of 0.15 would be stored as 15.

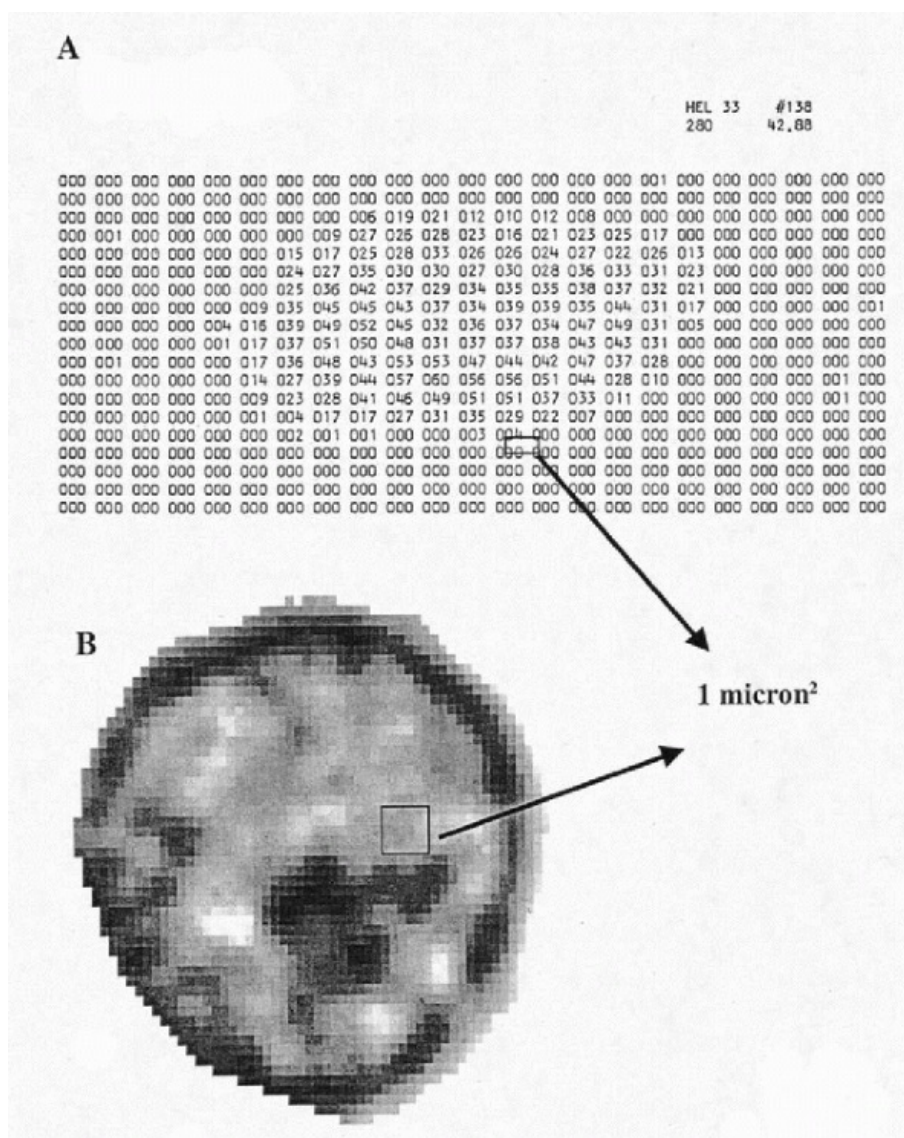

Figure 46-1 A The digitized image of human embryonic lung cell, recorded at 1 micron resolution. The numbers are "pixel optical density" values. B. An image of a hematoxylin-stained nucleus, recorded at 6 pixels per micron, and enlarged to show the pixelation.

Visual Versus Computed Image Information

Much of the information that can be derived from digitized imagery does not have a visual counterpart and provides **novel information of potential diagnostic value**. The difference between visual and computed image information is best demonstrated by a familiar example. Figure 46-2 shows a sample of printed text. A reader recognizes letters, words, and even the language: all of this is visual information. However, if asked "what is the relative frequency of occurrence

P.1683

of the vowel 'o' compared to that of the vowel 'e'?", no immediate answer can be given. Yet, these relative frequencies characterize the text and provide an objective, computed descriptive feature. One could ask how often is the letter "k" followed by the letter "l," or how often do two consonants follow each other? The pixel optical density values in a digitized image offer exactly the same kind of computed descriptive features in their 2-dimensional spatial and statistical distribution.

The potential of **digital diagnostic pathology and cytology**, though, far exceeds the mere statistical/descriptive representation of diagnostic evidence. Through power of variance-analytic procedures, the numeric representation allows the detection of subtle but consistently expressed differences between and among similar targets. **Computational procedures allow the detection of diagnostic evidence that is not readily perceived by visual examination.** Distinctive changes in the chromatin patterns of nuclei of benign cells in the presence of premalignant or malignant lesions are one example (Wied et al, 1980; Sherman and Koss, 1983; Bibbo et al, 1986; Montag et al, 1989; Bibbo et al, 1990; Palcic et al, 1994; MacAulay et al, 1995; Susnik et al, 1995; Bartels et al, 1998). Computer processing here truly expanded our ability to provide diagnostic information.

In the visual assessment of a malignant tumor, the information offered by the image is transformed by a pathologist into a “grade.” The equivalent in machine vision is direct mapping of a microscopic image to a numerically defined point on a continuous progression curve that may offer additional information beyond grade.

Quantification of diagnostic images requires accurate and precise data acquisition.

Image processing is then applied to the acquired data to extract diagnostic information, followed by numeric/analytic evaluation and diagnostic interpretation. In practice, one may distinguish between the digital assessment of cell images or nuclei, i.e., **cytometry and karyometry**, and the assessment of histopathologic sections, i.e., **histometry**. Of these, karyometry has proven to be particularly informative.

It is useful to distinguish three steps in the analysis of data: **image processing, image analysis, and image interpretation.**

In **image processing**, an algorithm that may be useful in subsequent extraction of diagnostic information is applied to the image. For example, a pixel optical density value threshold may be established, or a contrast-enhancing processing algorithm may be applied to define the targets of the study. In image processing, the input and the output are both represented by images.

In **image analysis**, specific diagnostic information is extracted from the image. Here, the first step is usually scene segmentation to delineate objects of interest; for example, the outline of a nucleus. While the input in image analysis is an image, the output is a set of “**features**”—**numeric values which characterize the sample and which contain diagnostic information.**

In **image interpretation**, the measures obtained from image analysis are evaluated by a mathematic/analytic process in order to assign a diagnostic label; for example, a cell may be classified as either normal or abnormal. The diagnostic label may also be a grade or a numeric value of a progression index established for a lesion or set of lesions.

Quantification of diagnostic image assessment involves methodologies derived from a wide range of scientific disciplines. It is the objective of this chapter to present an introduction to these methodologies and their theoretical bases and to illustrate each with practical examples.

SCENE SEGMENTATION

Procedures and Strategies

Scene segmentation is a crucial first step in quantitative image analysis (Abele et al, 1977; Weszka, 1978; Brenner et al, 1981; Juetting et al, 1983; Abmayr et al, 1987; Bartels and Thompson, 1994; Thompson et al, 1995). Any error in the delineation of objects propagates to the values used to define diagnostic features. For example, incorrect outline of a nuclear boundary is the principal cause for “false alarms” in automated screening for cervical cancer.

The problems with scene segmentation depend on the target. Under ideal circumstances, the microscopic image is based on a monolayer of single cells against a clean background, free of debris. At the other extreme, scene segmentation has to deal with complex imagery such as is seen in histologic sections of glands.

There are two distinctly different approaches to scene segmentation. The first is **image-oriented**. Here, the image in its entirety is processed by a segmentation algorithm. All objects in the scene are segmented by the same procedure.

The second approach is **object-oriented**. First, a search for “objects” is conducted, usually by applying an image processing algorithm, such as threshold-setting to the image. Then, each recognized object is outlined by a chaincode (see below) and stored (Freeman, 1961). Next, each of the stored objects is categorized and processed by a suitable segmentation algorithm. The object-oriented approach thus employs a flexible strategy, where different objects in the scene may be segmented by different procedures.

The **image-oriented approach has the advantage of simplicity and speed**. However, the selected algorithm may work well on some targets but fail with others. The **object-oriented approach** has a much higher software requirement and may be somewhat slower, but **can better handle complex imagery**. The result in both approaches is an outline of objects of interest, usually represented as a chaincode.

A **chaincode** is a list of values that begins with an x,y image coordinate for the first or start-pixel in the display, followed by a set of directions to the next pixel, etc. until the code returns to the start-pixel. One may define “the next pixel” depending on the system used. The definition is important because the approach to the pixelation of a small object may affect features such as perimeter length, object roundness, and object area (Bartels and Thompson, 1994; Neal et al, 1998).

Many segmentation algorithms are available. There are algorithms strictly based on the optical density of the object or pixel optical density thresholding. These may be used interactively by an observer who may adjust the threshold

P.1684

up and down until an object's outline agrees with the visual boundary. However, a fixed threshold may interfere with or “bleed” into the interior of the object to be outlined, as shown in Figure 46-3A, or be diverted from the desired outline by image background, as seen in Figure 46-3B. Simple thresholding frequently requires interactive corrections. A threshold may also be calculated using a histogram of pixel OD values by selecting a point of separation of two image regions. Various algorithms have been introduced to determine the differences in pixel OD value between an object and its background. Variations on these themes are algorithms that minimize some function to track the best boundary separating different objects in an image (Lester et al, 1978).

Figure 46-3 A. Segmentation by pixel OD thresholding. There is a risk of the threshold “bleeding” into the interior of the object. B. Failure of the segmentation algorithm to adhere to the object contour.

When objects touch or overlap, one may employ a **“shrink and blow” algorithm** (Fig. 46-4). Here, as the pixel OD value threshold is gradually increased, an indentation appears between two overlapping objects. The indentation deepens with the increasing threshold until the objects are finally separated. The algorithm then defines a segmentation line between them and expands the two new objects to the contours of the original single object. The sequence of processing is shown in Figure 46-5A—E. Similar algorithms find cusps—sharp concavities in the outline enclosing two touching objects. The algorithm determines which two cusps best correspond to each other and positions a segmentation line accordingly. One may segment an image by enclosing or outlining areas of particular color hue.

Figure 46-4 Finding of a segmentation line by a “shrink-and blow” algorithm.

Of particular value are **processing sequences based on mathematic morphologic image**

processing operations (Serra, 1983; Dougherty, 1992; Soille, 1998). Such operations allow all objects below a certain size to be eliminated, and the outlines of other objects to be corrected by smoothing and in-fill. The processing sequence developed by Juetting et al (1983) for the quantitative evaluation of thyroid follicles in fine needle aspirates are a good example, as shown in Figure 46-5A-E. The original image of a follicle is transformed into a histogram of pixel OD values. A threshold is set to outline nuclei. The resulting image is transformed to binary form. An erosion is performed to eliminate small particles of cellular debris and to correct small protuberances on the nuclear boundaries. By definition, a follicle includes a center or an interior region. A search for such interior regions is conducted within the thresholded image. The original binary image is segmented. Only the nuclei bordering the interior region are retained and stored as "follicle" for further analysis.

All these algorithms have a high success rate, **but rarely does one single algorithm segment all objects correctly**. An interactive correction is then required. This may be feasible when the number of objects is modest. For large images, however, full automation is mandatory, and the demanding requirements for a machine vision system have to be satisfied.

P.1685

The problem of scene segmentation in cytologic preparations proved to be one of the most challenging tasks in designing automated primary screening devices for cervical cancer. It is encountered with equal degree of difficulty in karyometry in histopathologic sections. Representative regions of a lesion may extend over several square millimeters. Using objectives with high numerical aperture, this translates directly into hundreds of video frames corresponding to the number of visual fields. Interactive correction of segmentation is no longer practical.

Figure 46-5 Processing of a scene by mathematical-morphologic operations. In *A*, the binary image of a thyroid follicle is shown. Note small debris is shown. *B*. The image after erosion, to remove small debris and smooth the nuclear outlines. *C,D*. The search for the interior region of the follicle. In *E*, only the nuclei forming the follicle are retained and segmentation lines are shown.

Histometric analysis increases the degree of difficulty. One is no longer dealing with a processing task that is concerned with separate, well defined objects, such as nuclei. Instead, the histologic section is composed of adjacent components that represent a variety of structures. Processing steps to find a segmentation line for one component may adversely affect correct segmentation for other structures. The entire scene is combined or “coupled” in its processing requirements. **Scene segmentation for histopathologic sections has finally become tractable by the development of knowledge-guided procedures** (Liedtke et al, 1987; Thompson et al, 1993, 1995, 1996). In a knowledge-guided process, information, not offered by the image itself, is used to control the scene segmentation. This principle was first employed by Liedtke et al (1987) in the segmentation of cervical cytologic materials. Knowledge-guided process control now has been applied to the automated segmentation of prostate lesions, colonic tissues, and breast lesions (Anderson et al, 1997).

Megapixel Arrays

The first task faced in an automated analysis of histopathologic sections is the recording of the very large pixel arrays required to capture an entire diagnostically representative region (Bartels et al, 1995; Bartels et al, 1997; Ott, 1997).

For the **recording of histopathologic imagery** a wide field objective $\times 25$ with a numerical aperture of 0.75 is a good choice. Such an objective typically covers a field of 750 microns in diameter, or a square image tile of around 500 microns in side length. For image sampling, the diffraction limit of the objective must be matched with the CCD elements of the video camera. Some oversampling must be allowed. This determines the choice of the relay optics (Hansen, 1986; Bartels, 1990; Baak, 1991). For a 5×5 mm region of a histopathologic section, this system generates 100 video frames, or an image array of 100 megapixels. Within such an array, processing and analysis of histologic structures are no longer limited by the optical image, though the seamless merging of the 100 image tiles is difficult. Two major difficulties must be controlled. First, the orientation of the CCD array and the direction of travel of the computer-controlled microscope stage must be aligned with great precision and rigidly maintained. Even so, some software adjustment during tile merging is usually required. Second, seamless joining of tiles should occur even when the merge line intersects a nucleus. These goals can be achieved by cross-correlation procedures allowing for a region of overlap (Thompson et al, 2001). Figure 46-6 shows a 100 megapixel array for a prostatic carcinoma. Images such as this are recorded at full resolution and then pixel averaged for display at different magnifications. Such images may be instantly recalled. Figure 46-7 shows a nucleus dissected by the merge line.

Figure 46-6 Multimegapixel array of a digitized section of prostatic carcinoma. The image is stored at full resolution, and may be recalled for any location and at any wanted reduction for display.

Knowledge-Guided Scene Segmentation

Knowledge-guided scene segmentation provides the means for **autonomous processing of imagery from a specific visual target**. The knowledge-guided system should be able to segment any scene from the target in a fully automated fashion and without errors.

The principal **difference between visual perception** of a

P.1686

microscopic image and the information **evaluation by a machine vision system** is that human vision perceives the entire scene simultaneously. Every object and structure is revealed in their relative position. A machine vision system acquires the data sequentially. It is "pixel-bound" in processing of the image, i.e., tied to the pixel currently being processed and its immediate neighbors. Human image assessment is supported by information not offered by the image itself, such as the professional experience of a diagnostician, knowledge of anatomy, histology, pathology, and knowledge of the relationships between structure and function. If one expects a machine vision system to perform at a comparable level, then such information must be made available to its control software. This information may be offered to the machine vision system in the form of a **knowledge file** (Bartels et al, 1992). A **knowledge file** will hold a large amount of generally applicable information, as well as very specific processing instructions for a

particular and narrow diagnostic target or domain, for example, prostatic intraepithelial neoplastic lesions or a poorly differentiated prostatic carcinoma.

Figure 46-7 Tile merging based on cross-correlation techniques, showing the exact match of structures from both tiles down to the pixel level.

A **knowledge file** consists of two major sections. In a first declarative section, all entities pertaining to a given domain are listed, with their properties, the computer operations required for their evaluation, and the sequencing of these operations. The entities entered into the knowledge file may fall into two logical groups. The **first group consists** of all entities recognized by the human eye, such as the nucleus, cytoplasm, various cell types, etc. The **second group** consists of entities that are solely related to image processing and constructs known as “intermediate segmentation products.” Examples of entities that are solely related to image processing could be red image, pixel, pixel OD value threshold and area, as well as subroutines, algorithms, and functions constructed to define a segmentation procedure, for example, a function that finds objects of interest.

Intermediate segmentation products are objects produced by machine vision segmentation during the initial processing phase aimed at detecting image regions that can be separated from the background. Some of these outlined objects may be well-defined morphologic components such as a single nucleus. Others may be objects that require further segmentation, e.g. a cluster of overlapping nuclei. Others may be fragments of one or more histologic components, such as secretory epithelium or portions of two different glands that appear in machine vision to be a single object. Figure 46-8 shows a brief processing sequence of segmentation of glandular epithelium. In Figure 46-8A, a portion of the glandular epithelium has been correctly recognized and segmented, but the gray-shaded glandular epithelium on the left belongs to three different glands. It is an intermediate segmentation product. In Figure 46-8B, the section of epithelium belonging to the gland on the lower left has been recognized, and so has the remaining segment of epithelium for the gland on the right. But, an intermediate segmentation product, now comprising segments from two different glands, still remains in need of further

segmentation. Figure 46-8C indicates the segmentation line that the system found. In the next step, both of the remaining epithelial segments would be correctly assigned to their glands.

Human vision immediately identifies these intermediate segmentation products. A machine vision system needs to be given explicit instructions on how to recognize the objects and how to process them. Fortunately, only a limited number of different intermediate segmentation products occur for scenes from a given domain. They must be specified by name as separate entities in the knowledge file, to allow the control software to call on the appropriate next processing sequence.

Figure 46-8 Processing sequence of a knowledge-guided segmentation. In *A*, the glandular epithelium from three glands remains connected, as an intermediate segmentation product. In *B*, the segment belonging to the gland in the right center is correctly segmented and added to that gland. In *C*, a portion of the epithelium belonging to the gland at the center left is correctly recognized and segmented. The glandular epithelium from the large gland at the top is assigned to that gland and a segmentation line has been drawn.

The **second section of the knowledge file** contains definition statements. It gives specific processing instructions to find the required entities and also can logically relate the entities from the first two subsections to each other. The definition statements are written in a subset of English, e.g. a nucleus is an object with size (limited by constraints) and with shape (limited by constraint) and with total optical density (limited by constraint).

The knowledge file is a text file and may readily be amended or modified. It is read by the control software and consulted at run time. As the software interprets the definition statements, it sets up a node and processing sequence for each entity. The results obtained during the scene processing must satisfy the constraints at all the nodes.

P.1687

Relatively simple targets or scenes, such as tissue from well-differentiated adenocarcinoma, require approximately 100 entities to allow successful segmentation for 90% to 95% of all scenes. More complex scenes have required approximately 250-300 entities to provide segmentation at the same rate of success (Thompson et al, 1995).

The **complete segmentation process involves two major phases**. In the first, the scene is segmented until every object is either recognized as a correctly outlined histologic entity, as listed in the knowledge file, or as a fragment of such an entity. In the second phase, the scene is reconstructed from the objects on file. In this operation, the control software has to check for logical consistency of the reconstruction. The extraction of histometric diagnostic information is begun only after scene segmentation, reconstruction and consistency checks have been completed.

A knowledge-guided scene segmentation system constitutes a major software development. The machine vision system at the Optical Sciences Center, University of Arizona, comprises some 20,000 lines of control code and image processing code. Structurally, the control software is an **expert system** implemented as an associated network with frames at each node (Jackson, 1986). There the specific results from the processing of each object are accumulated for later use.

Systems capable of segmenting, analyzing and interpreting imagery in a fully autonomous fashion, guided by a source of external knowledge of the domain and the processes required have become known as **image understanding systems** (Bartels et al, 1989).

Figure 46-9A-D shows the result of an automated segmentation of a tissue section from the prostate. Sample fields showing segmentation of lumen, stroma, secretory, and basal cell nuclei, and basal cells only are shown as a sidebar.

Figure 46-9 Automated segmentation of a tissue section from the prostate. The regions identified by the machine vision system as lumen, stroma, nuclei of the glandular epithelium, and basal cell nuclei alone shown in black in the small demonstration windows. Actually, the entire image is segmented automatically.

EXTRACTION OF DIAGNOSTIC INFORMATION

With images correctly segmented and all objects of interest properly outlined, diagnostic information collection can begin with “feature extraction.”

Features

Features are descriptive entities that have numerical values. They may represent traditional diagnostic entities, such as “nuclear area” or “nucleocytoplasmic (N/C) ratio.” They may represent the spatial and statistical distribution patterns of nuclear chromatin in terms that may not have a direct visual equivalent, such as the frequency of co-occurrence of optical density (OD) values in certain range of pixels adjacent to each other. Feature extraction results in an invariant representation of an object from the image that is now characterized by a set of features.

In cytometric analysis, information of diagnostic value is offered at several different levels.

There is information at the pixel level where only the properties of individual pixels are considered. This information is often used in scene segmentation to define a boundary based on pixel OD value, or pixel OD value gradient between pixels, or pixel OD value differences between images from different spectral bands.

There is **information at the feature level** when groups of pixels form a feature. The properties of such pixel groups are considered a **feature value**. The variance of all pixel OD values in a nucleus is an example.

One may transfer feature evaluation from absolute feature values to a relative scale, where all feature values are expressed in units of deviation from a "normal" reference. This makes feature evaluation less sensitive to specimen preparatory effects. Using the standard deviation of features in the normal reference data set as a unit, feature values are expressed in z-values or as relative deviation from normal.

It is customary to present all feature values in relative units because most features depend in their value on the sampling density in the image. Also, for purposes of multivariate analysis, it is advisable to have all variables of roughly the same order of magnitude.

For **feature extraction from cytopathologic preparations and karyometric measurements**, a set of approximately 100 features is commonly used (Bartels et al, 1980; Bengtsson et al, 1994; Doudkine et al, 1995). These features fall into distinct groups. There are features which represent an object as a whole, such as the nuclear area, total optical density, N/C ratio, variance of pixel OD values, shape features, measures of roundness of a nucleus, of concavities in the boundary or ellipticity. This group of features is often referred to as **global features**.

P.1688

DNA PLOIDY ANALYSIS

The **total optical density** is one of the most often utilized global features. It is computed as the sum of all pixel optical density values within the boundary of a nucleus. It is usually expressed in arbitrary units.

Total optical density is used in dual mode, either as a descriptive feature in image analytic cell recognition, or as a quantitative cytochemical procedure, particularly DNA ploidy analysis in Feulgen-stained samples.

The Feulgen procedure (Feulgen et al, 1924) results in a stoichiometric staining of the nuclear DNA (see Chap. 44 for technical details). The total optical density measured on nuclei prepared in this fashion provides **a quantitative measure of the nuclear DNA content** which may be useful in diagnosis and grading of tumors (Boecking et al, 1994).

The **principles** of DNA ploidy measurements by image analysis are simple. The total optical density value for each individual whole nucleus is used to construct a **histogram**. From 100 to 1,000 nuclei, with an average of 300, must be measured to construct a reliable histogram. The distribution of the DNA values in a histogram of the unknown target is compared with the distribution of DNA values of a normal cell population. The latter may be **haploid** (1N) as observed in germ cells, such as human spermatozoa containing 23 chromosomes, or **diploid** (2N) containing double the number of chromosomes (46 in humans) as observed in all somatic cells. **The number of chromosomes is proportional to DNA content**. A further important variant is caused by **cycling cells that double their DNA content during the S phase of the mitotic cycle**. Thus, a histogram of normal DNA values of cycling diploid cells will show

cells in G₀G₁ (2N) phase of the cell cycle, followed by gradual increase of the DNA content during the S phase, until double the original DNA content (4N) is reached during the G₂M phases of the cycle, prior to cell division. Normally, the G₂M peak is very small.

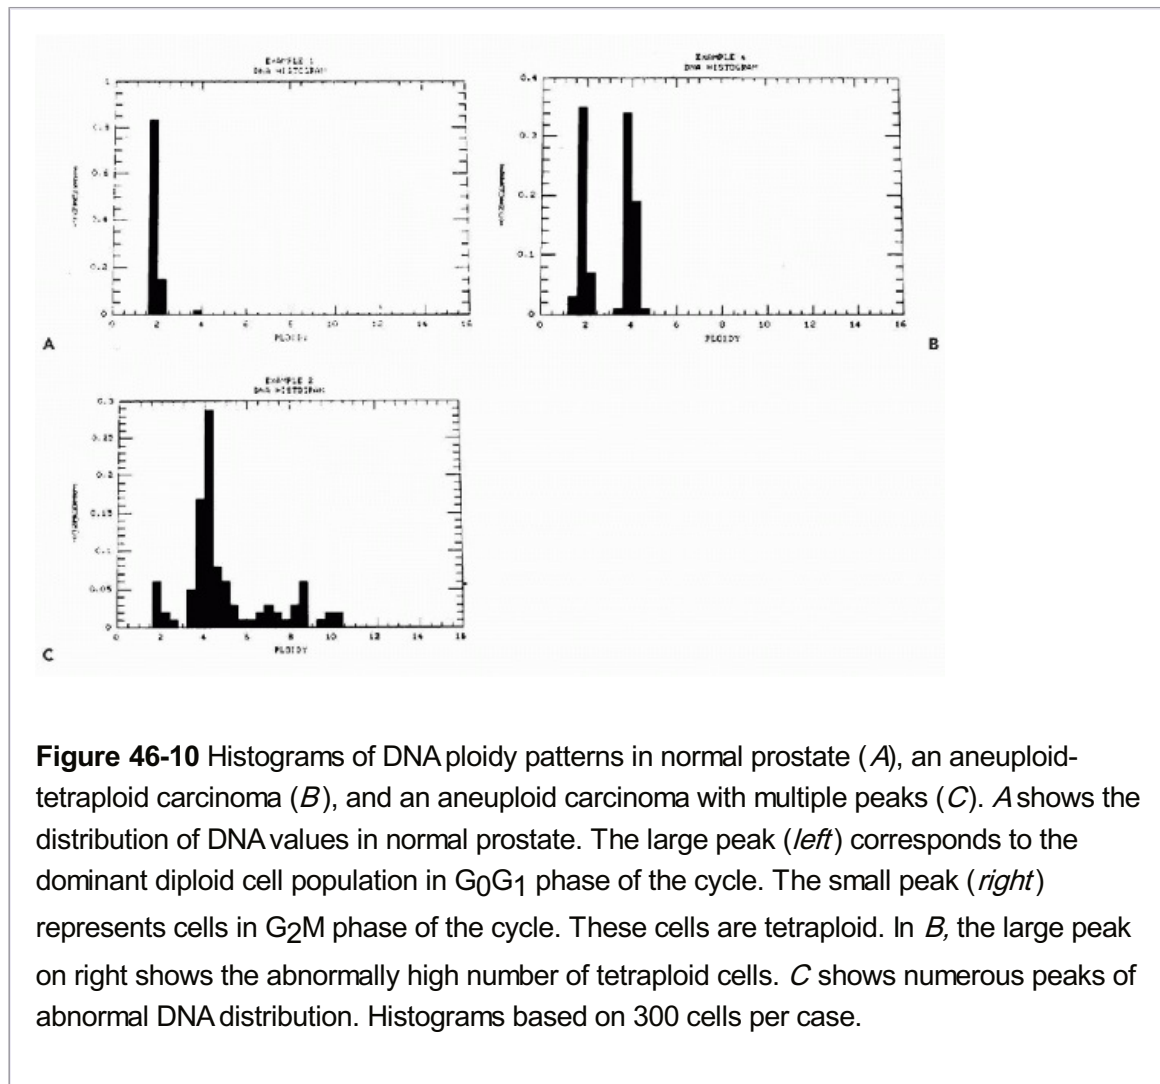

Figure 46-10 Histograms of DNA ploidy patterns in normal prostate (*A*), an aneuploid-tetraploid carcinoma (*B*), and an aneuploid carcinoma with multiple peaks (*C*). *A* shows the distribution of DNA values in normal prostate. The large peak (*left*) corresponds to the dominant diploid cell population in G₀G₁ phase of the cycle. The small peak (*right*) represents cells in G₂M phase of the cycle. These cells are tetraploid. In *B*, the large peak on right shows the abnormally high number of tetraploid cells. *C* shows numerous peaks of abnormal DNA distribution. Histograms based on 300 cells per case.

If the unknown sample shows a DNA distribution equal to normal, it is considered to be **diploid**. If the histogram of the unknown sample shows values not consistent with normal distribution, it is considered to be **aneuploid**. There are various forms of aneuploidy, depending on the position of the peaks. A sample can be **hypo- or hyperdiploid**. The latter may occur as single or multiple peaks in the histogram (Fig. 46-10). The term **stemline** is often used to define a single population of aneuploid cells. Thus, a tumor may have a single or multiple stemlines.

The procedure requires strict adherence to protocol (Boecking et al, 1995; Schulte, 1991). To maintain stoichiometry of staining one will have to ascertain that cells of different phenotypes, mainly reference nuclei and target nuclei, are equally affected by the hydrolysis step in the Feulgen procedure (Schulte et al, 1990). Additional problems may be experienced if attempts are made to estimate minor histogram abnormalities, such as the estimate of an S-phase fraction or detection of a near diploid stemline. In practice,

P.1689

the interpretation of a DNA content histogram or "ploidy pattern" may not go farther than a visual assessment of whether aneuploidy is present.

The most reliable results are obtained using formalin-fixed cells in smears. **Measurements of**

DNA ploidy on tissue sections are generally not considered to be of comparable quality, or even not as acceptable at all. Corrective measures have been suggested to allow for the effects of section thickness and nuclear transection. However, even the reference nuclei used to establish the position of the 2N peak may have different sizes, geometry and orientation within the section.

Today, **cell cycle analysis, S-phase fraction** estimates and high-resolution stemline detection are usually performed by **flow cytometry** (see Chap. 47). **However, image analysis is the preferred procedure when the cell sample is small**, when it is essential that only tumor cells be included in the sample, by visual selection, or when one wishes to detect the presence of rare cells with abnormal DNA content.

The two methods are mutually complementary and are compared in Table 47-3 in the next chapter.

DNA ploidy measurements by image analysis have been applied to human cells and tissues, usually to elicit **differences between benign and malignant tumors and differences among malignant tumors of the same origin to elicit data of prognostic value** (Auer et al, 1980; Baak, 1991). In Chapter 47, the reader will find information pertaining to ploidy measurements in specific human tumors.

Pixel Optical Density Histogram

The histogram of pixel OD values typically consists of 18 features. Each of these is the relative frequency of occurrence of pixels in an optical density interval 0.10 units wide, spanning the range from OD 0 to ≥ 1.8 . The relative frequency of occurrence of pixels in a given OD interval is a first order statistic. The count depends only on the single pixel whose value is observed. This count is not dependent on the values of other pixels in the vicinity. The pixel OD value histogram is used primarily to compare two populations. Figure 46-11 shows the histograms for a normal cell line and for a malignant cell line (Wied et al, 1968). One notes the shift of the histogram mode to high pixel OD value, in the malignant cell line, reflecting the presence of denser chromatin granules in the nuclei. The relative frequencies of occurrence of pixel OD values of nuclei are very useful in diagnostic cell classification. Their differences in a given pixel OD value interval, and the scatter about the two respective mean frequencies of occurrence, determine how well the feature "relative frequency of occurrence (dn/n) in a certain optical density interval" allows a discrimination between diagnostic categories A and B (Fig. 46-12).

Pixel OD value frequencies have been used extensively. **They are robust and reliable features that reflect nuclear chromatin texture** and are often the first to undergo a significant change as cells respond to changing conditions.

The pixel OD value difference histogram may be used to assess the granularity of nuclear chromatin. The pixel OD value co-occurrence matrix provides a set of features that is based on the probability that a pixel in a certain OD

P.1690

value range is followed (along the scan line) by a pixel within a certain OD value range (Bartels et al, 1969; Haralick et al, 1973; Pressman, 1976). The co-occurrences are second order statistical features. Typically optical density ranges 0.30 units wide are chosen. Thus, the range from OD 0 to ≥ 1.8 is covered by six intervals. This yields 36 features for the co-occurrence matrix. In practice, only half of the matrix is used and the co-occurrences of pixels in ranges i,j are considered the same as from the ranges j,i . Table 46-2 shows such a co-occurrence matrix, with entries normalized to unity for the full row; here only the entries for the upper diagonal are

shown.

Figure 46-11 Pixel optical density histograms for a normal and a malignant cell line. Note the extension of the pixel optical density values into the higher optical density range in the malignant cells.

Figure 46-12 For the information offered by the pixel optical density histogram, the relative frequencies of occurrence of values in the different optical density intervals are the variables. The two horizontal axes are those relative frequencies of occurrence and the pixel optical density values. The histograms are shown for two cell types *A* and *B*. The two histograms have well separated relative frequencies of occurrence in the interval *i*, as shown. The vertical axis indicates the relative frequency of occurrence of nuclei having pixels in the optical density interval *i*, from cell type *A* and *B*.

TABLE 46-2 CO-OCCURRENCE MATRIX

Optical Density Ranges	0.01- 0.30	0.31- 0.60	0.61- 0.90	0.91- 1.20	1.21- 1.50	>1.50
0.01-0.30	0.76	0.16	0.08			
0.31-0.60		0.69	0.16	0.12		
0.61-0.90			0.58	0.22	0.06	
0.91-1.20				0.41	0.35	
1.21-1.50					0.38	0.02
>1.50						

A sequence of pixels with OD values occurring in the same interval is called a “run.”

Run length analysis is well established for texture assessment (Galloway, 1975). The run length

features in cytometry and karyometry typically involve several length intervals, e.g., runs of length 1-2, 3-4, 5-6, 7-8, 9-10, or 11-12 pixels. When the run length is evaluated for six OD intervals, one again obtains a block of 36 features, or run length counts. The set of run length features describes higher order statistical dependencies of a textured field, such as formed by the nuclear chromatin. From the co-occurrence and the run length matrices, summarizing features have been derived, such as short run emphasis and long run emphasis, run length uniformity and run length non-uniformity (Doudkine et al, 1995; Young et al, 1986). Other features directly describe the spatial distribution of nuclear chromatin. There are measures of peripheral tendency of the chromatin and of chromatin clumpiness. The above-described set of features has been found useful to characterize the spatial and statistical distribution of chromatin in all types of nuclei.

Histometry

In histometry, the features are generally more specific and better defined for diagnostic assessment. The features are not readily transferable to other applications. Examples of histometry are the measure of the disruption of the basal cell layer in prostatic intraepithelial neoplasia (Bartels et al, 1998), measures of complexity of cancerous prostatic glands (Anderson et al, 1997), or measures to determine the number of cell layers in a secretory epithelium (Hamilton et al, 1995). All of these tasks require full scene segmentation. There are other histometric measures that do not require intensive image analysis prior to feature extraction. Graphs and nets (simple decompositions) provide measures for nuclear placement patterns. These, in turn, may be used to quantify tissue de-differentiation. Examples are construction of a minimum spanning tree (Fig. 46-13) or of a Voronoi tessellation (Voronoi, 1902),

P.1691

as shown in Figure 46-14. Such a decomposition yields sets of features, such as the number of branches in a graph, the link length distribution, the number of vertices, the number of neighbors for each vertex, and the distribution of angles at the vertices. These features are then further processed by standard discriminant analytic procedures. The type of analysis has become known as **syntactic structure analysis** (Kayser, 1988; Rodenacker et al, 1988).

Figure 46-13 Example of a minimum spanning tree. A set of nuclei is connected, from nuclear center to nuclear center by the shortest possible connecting links. From such a minimum spanning tree descriptive features for the nuclear placement can be derived.

Figure 46-14 Example of a Voronoi decomposition. Nuclear centers are connected into a grid and features such as the link length distribution, number of segments, shape of segments, link angles can be derived to describe the nuclear placement.

Diagnostic Information

Many of the analytic procedures used in cell classification were adopted from methods used in pattern recognition. Most are based on mathematical/statistical algorithms (Agrawala, 1977; Fukunaga, 1972). They have served the field very well indeed. The classification performance deteriorates when more than about a dozen features are employed. One may, of course, select the strongest features, whose distributions for different categories of cells have minimal overlap and a high likelihood of membership in a given category. Yet, considering that about 100 features are routinely computed, the methodology seems to waste diagnostic information. If the values of all measured features are arranged in an arbitrary but consistent order, one obtains a profile which expresses values and correlations among all of the measured features.

Normalizing feature values gives them comparable value ranges. Each feature value may be expressed in units of standard deviation as determined on a reference data set of normal nuclei from the same tissue, i.e., one might use **“deviation from normal,” or a z-value**. Such relative measurements add stability and are a rich source of diagnostic information. Figure 46-15 shows such z-value profiles for normal nuclei of intermediate squamous cells from the cervix and for nuclei from cells derived from a high-grade precancerous lesion. These profiles are called **“nuclear signatures”** (Bartels et al, 1998; Mariuzzi et al, 2000).

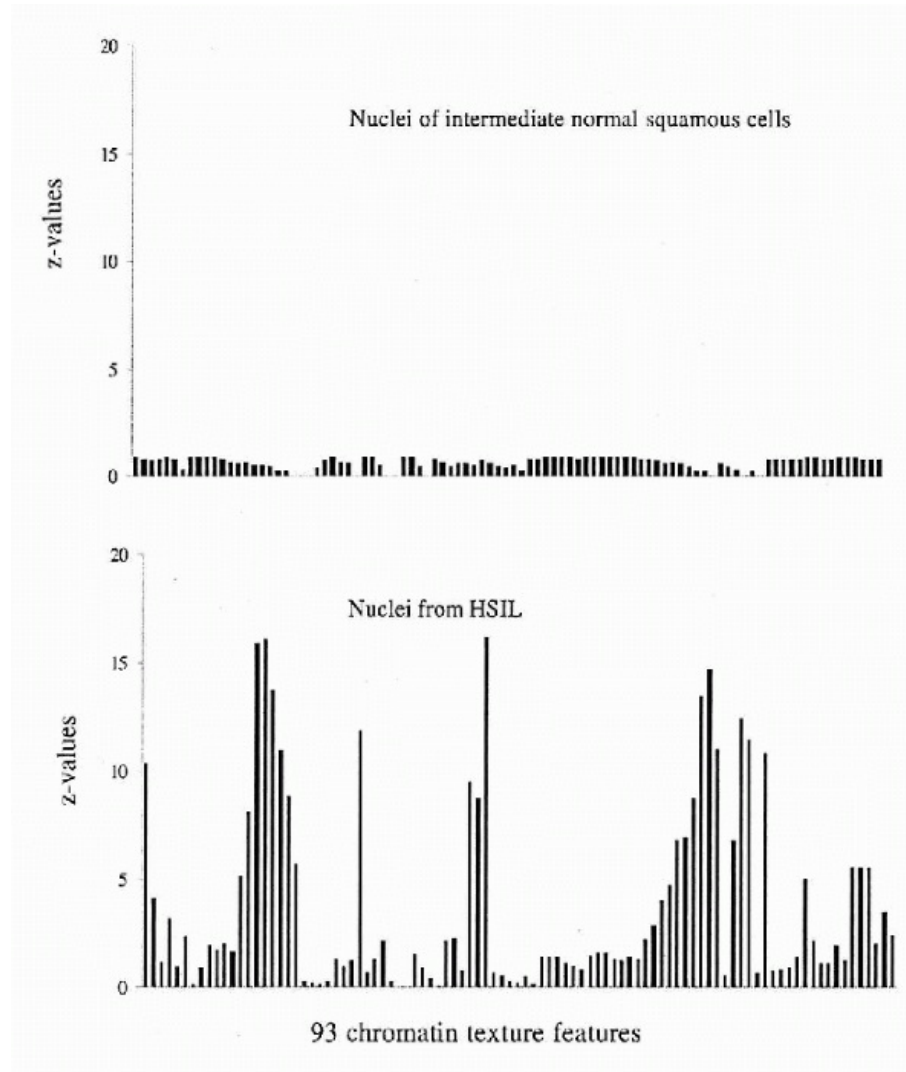

Figure 46-15 Nuclear signatures for intermediate squamous cell from the cervix, and for nuclei from HSIL. The abscissa represents 93 karyometric features, arranged in an arbitrary, but consistent order. The ordinate expresses the deviation for each feature from values found in a set of normal reference nuclei (*top*), given in units of standard deviation (z-values).

The nuclear signature clearly shows the so-called **malignancy associated changes (MAC)** in the nuclear chromatin (see Chap. 7). Figure 46-16 shows the **nuclear signatures** for visually normal intermediate cells from the normal cervix

P.1692

and for visually normal intermediate cells from a cervix with a dysplastic lesion of a moderate grade. The nuclear signature of the latter resembles that from nuclei derived from a low-grade precancerous lesion.

Figure 46-16 Plot of abnormality for nuclei from normal intermediate cells from the cervix, for visually normal appearing intermediate cells from the cervix harboring a low-grade dysplastic lesion, and moderate grade dysplastic lesion, and for nuclei from low-grade dysplasia and high-grade dysplasia. Also shown are the nuclear signatures. The nuclear signature of visually normal appearing intermediate cells from cases of low-grade dysplasia clearly indicate the presence of that lesion.

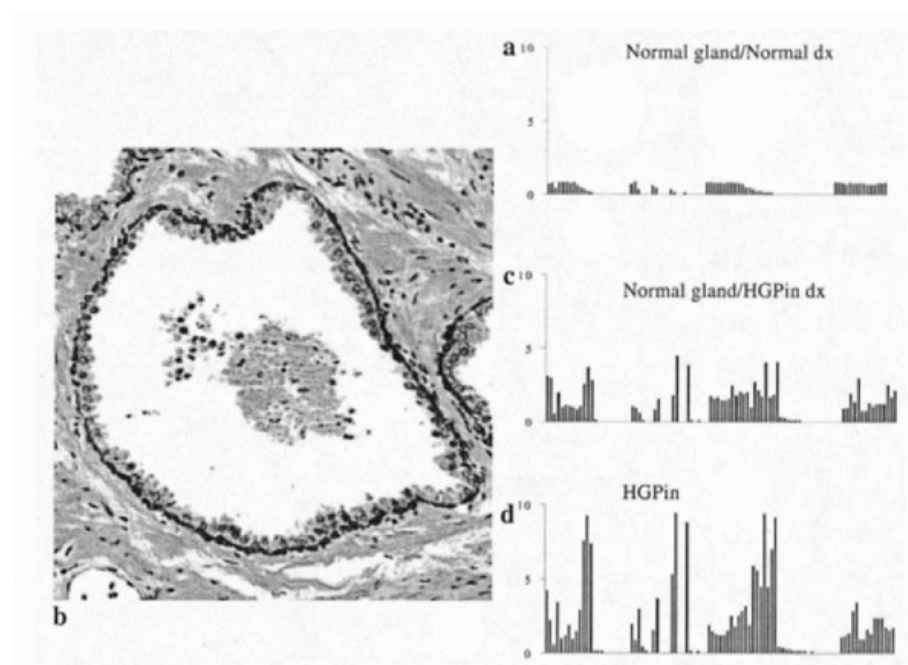

Figure 46-17 Demonstration of the expression of "malignancy associated changes" in prostate tissue. *A*. The nuclear signature of nuclei from secretory cells from prostate free of any premalignant lesion. *B*. A prostate gland from histologically normal-appearing region of a prostate harboring a high-grade intraepithelial neoplastic lesion. Its visually normal appearing nuclei show a nuclear signature (*C*) that clearly resembles the signature of

nuclei found in the high-grade PIN lesion, seen in *D*.

In tissue sections of normal prostate, the nuclear signature of secretory cell nuclei is shown in Figure 46-17A. In Figure 46-17C, the signature of the nuclei from the prostatic gland (Fig. 46-17B) is seen: the nuclei already exhibit a signature that suggests the presence of a high-grade malignant lesion in the organ. The nuclear signature of nuclei measured directly in such a lesion is shown in Figure 46-17D.

The **profile of z-values, or deviations from normal for each feature**, offers two kinds of novel information. Z-values averaged over all features, provide a measure of nuclear abnormality. This may be used to derive a lesion signature. A **lesion signature** is simply the distribution of nuclear abnormality values for a representative sample of nuclei from a given lesion. Figure 46-18 shows lesion signatures for normal endometrium, atypical hyperplasia and adenocarcinoma of the endometrium.

Figure 46-19 shows lesion signatures for morphologically normal intermediate squamous cells from a normal cervix and for microscopically identical cells from patients with various grades of dysplasia, expressing malignancy associated changes. Figure 46-20 shows lesion signatures of an intraductal carcinoma in situ of breast.

The next step is data analysis that leads to an evaluation of the set of nuclear features to allow the interpretation of the data.

DATA ANALYSIS

The common objectives of an analysis are one or more of the following:

Figure 46-18 "Lesion signatures" for endometrial tissues.

- To characterize cells or tissues in numeric form using their descriptive statistics
- To detect and document small differences between or among cells or tissues
- To define procedures for the assignment of cells or tissues to a diagnostic category: classification and diagnostic decisions
- To determine whether a set of nuclei forms a homogeneous population or if subsets exist
- To assess progression of a lesion

Multivariate procedures exist for each of these tasks. It is useful to understand which of these "tools" is best suited for a given analytic objective. The analysis of data usually **requires multiple programs** that must be coordinated as software modules.

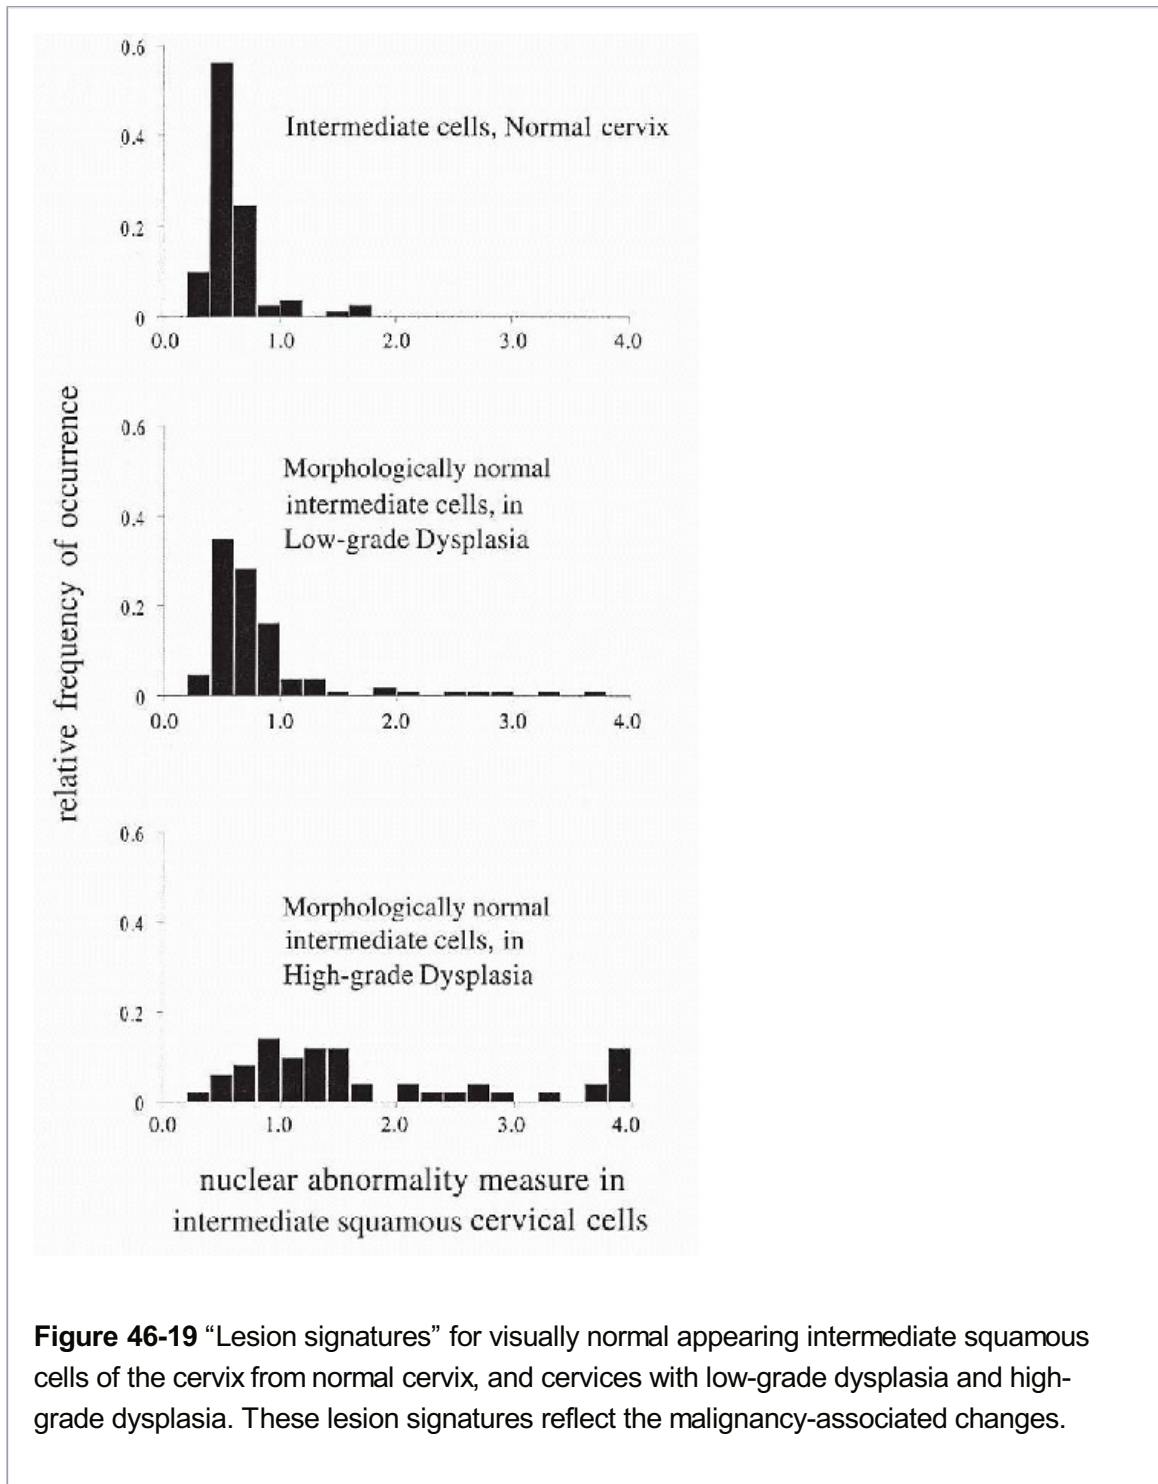

Descriptive Statistics

Descriptive statistics characterize a set of objects, such as cells or nuclei, by the numeric

values of their features. The mean values and the standard deviations of the features are computed. Occasionally, the correlation coefficients for certain pairs of features are calculated. The underlying assumption in these calculations is that a data set is homogeneous and representative of a diagnostic category. Not uncommonly, however, mean values and standard deviations for a given feature differ between and among cases and preparations confounding the effects of random variations. To avoid this pitfall, it is advisable to estimate the descriptive statistics after an analysis of variance has provided an estimate

P.1693

of the standard deviations pertaining to the case to case and nucleus to nucleus variability.

The detection of small differences between and among biologic targets, such as cells, is a frequent analytic task. The ability to document differences too small to be unequivocally appreciated by visual observation is one of the great advantages of digital analysis. The significance of small differences in the values of a feature between two data sets may be established by a number of test statistics, such as **Student's t-test**, the **U-Whitney test**, or a **Kruskal-Wallis (KW)** test (Bradley, 1968). However, the full power of detection by statistical analysis comes into effect only by a **skillfully planned experimental design for an analysis of variance** (Ostle and Mensing, 1975; Sokal and Rohlf, 1969).

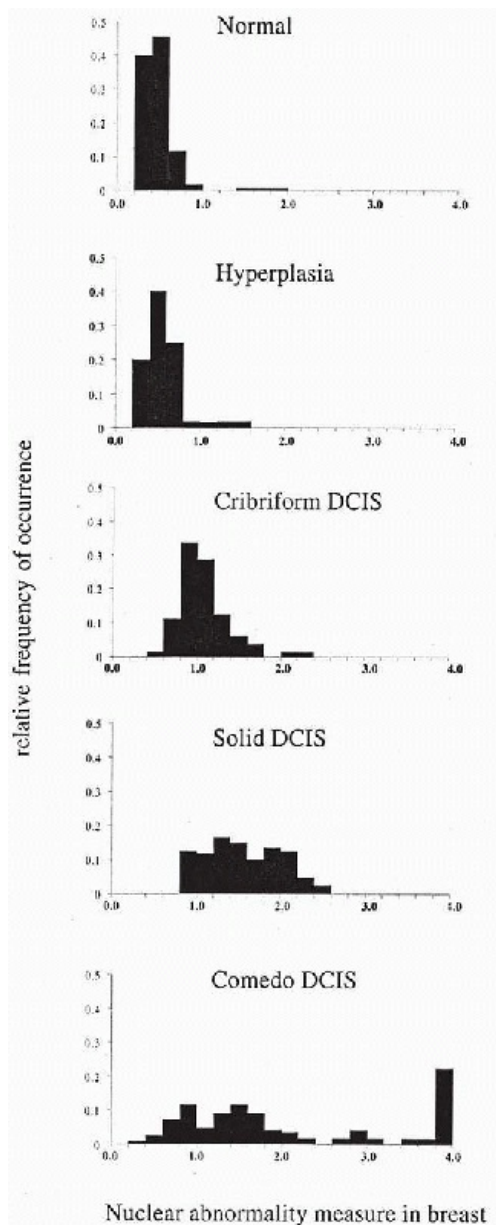

Figure 46-20 Lesion signatures for intraductal carcinoma in situ of breast. DCIS, ductal carcinoma in situ.

The significance of a difference is shown when the confidence limits at a specified level, for example, 95% for the

mean values in two data sets, do not overlap. The results depend on the standard deviation of the measurements.

TABLE 46-3 NESTED ANOVA ANALYSIS OF VARIANCE FOR THREE DIFFERENT GRADES OF A LESION

Source	SS	df	Mean square	% Mean square	F-value	p
Dx/Grade	7.280	2	3.640	72%	4.25	<0.025
Case	28.2635	33	0.8565	17.0%	1.60	<0.05
Nuclei	366.15	684	0.5353	11.0%		

Dx = diagnosis; SS = sum of squares is the sum of all squared deviations from the mean; it measures the variability in the data set; df = degrees of freedom reflects the number of observations that are considered at each level of the nested design; ms = mean square is the sum of squares for each nested level, divided by the applicable degrees of freedom. Thus, it simply is the variance component associated with that level, e.g., case to case variability; F-value = a variance ratio test. See text for further analysis of data.

An **analysis of variance** allows one to determine the causes of the observed differences. By clever experimental design, one can estimate exactly how much each cause affects the variance and assign certain proportions of it to known effects. The remaining “unexplained” variance is much smaller and may detect much smaller significant differences that could not be observed prior to the analysis of variance. This powerful technique allows highly significant results to be documented with a minimum amount of data collection. There are literally dozens of different “designs” for analysis of variance. Two such designs are particularly useful in quantitative cytopathology.

The first is a **nested design** (Sokal and Rohlf, 1969). It allows one to determine the significance due to the principal assumption (such as diagnosis) and to estimate the proportions of variance due to case to case variability, sampling heterogeneity and variability among targets (such as nuclei). To establish a difference between two diagnostic categories, one has to show significance of its variance component over the variance component caused by case to case mix. The nucleus to nucleus variance component serves as the general error term. Table 46-3 provides an example. A diagnostic feature was measured for nuclei from three different grades of a lesion. Twelve cases were studied and 20 nuclei were measured from each case. This leads to a nested design with “grade” as first level, “cases” as second level, and “nuclei” as the third level. The differences between grades are statistically significant. Seventy-two percent of the total mean square is due to the differences between grades and only 17% is due to case to case variability.

The second experimental design of practical interest is a **factorial arrangement of treatments** (Sokal and Rohlf, 1969). It allows one to test for the existence of “interaction” or

synergistic effects. This approach may address questions such as: are the nuclei from certain lesions more abnormal than those from other lesions even though diagnostic grades were the same? Are some patients responding to a treatment and others not?

CLASSIFICATION AND DIAGNOSTIC DECISION PROCEDURES

The derivation of a rule that allows one to assign unequivocally a cell to a diagnostic category on an objective basis is one of the most common analytic goals. It is also a task that is far from straightforward. A diagnostic decision based on numeric data derived by an analytic procedure may be based on one of two different paradigms: multivariate/statistical procedures (Bartels et al, 1986; Clifford et al, 1975; Hand, 1981) or accumulation of likelihood procedures (Jensen, 1996; Pearl, 1988). Many methods of classification exist.

In **multivariate mathematical/statistical procedures**, a set of variables—representing diagnostic criteria—is recorded. They are each appropriately weighted and entered into a classification function. A function score is computed, compared to a threshold, and an assignment to a diagnostic category is made. Examples discussed below are supervised learning and unsupervised learning.

The **second paradigm** follows more closely the process of a human diagnostician. Diagnostic evidence is recorded. An estimate is made as to how the observed outcome of the first diagnostic criterion affects the relative likelihood for each of the alternate diagnostic categories. Then the next diagnostic criterion is observed and evaluated. The assessment of the likelihoods for each diagnostic alternative is updated according to the newly entered evidence. This is continued until the certainty for one of the diagnostic outcomes has reached a very high value.

There are substantial differences between these two approaches. The mathematical/statistical algorithms work in a closed feature space, i.e., only those features effective for discrimination are evaluated. No further information is extracted from the clinical material after that. The number of features in a classification function is typically less than 10, although in hierarchic classifier designs, more features might be employed. The same features are evaluated for every object. The algorithms cannot tolerate missing feature values.

P.1695

The **second paradigm** operates in an open feature space: as many diagnostic criteria are evaluated as are needed to reach the required level of certainty for assignment to a diagnostic category. The procedure allows substituting different features if certain diagnostic clue values are not expressed and missing. Thus, different criteria may lead to object assignment to a given category. The process does not involve an estimate of a multivariate probability density function. Hence, one may use a larger number of features than a statistics-based algorithm would allow. Examples of this paradigm would be inference networks (Bartels et al, 1992) and automated reasoning systems (Bartels et al, 1996).

Supervised Learning: Statistical Procedures

Supervised learning is based on the analysis of two sets of objects (i.e., nuclei) classified a priori in two categories. These nuclei are used as **training sets**, to derive a classification rule that is tested on a **test set**. To establish a training set, the processing steps are:

- Computing feature values
- Feature selection to reduce the dimensionality

- Processing by a classification algorithm
- Estimate of correct classification rate for the training sets
- Application of classification function to a test set (i.e., data of known diagnostic label that were not used to derive the classification rule)
- Estimate of correct classification rate for the general case

A basic assumption in statistical classifiers is that the nuclei in each training set are of homogeneous phenotype. It is possible to compute the values of 100 different features for each nucleus. However, since classification algorithms typically accommodate, at most, 10-15 features, only the best features are selected in order to reduce the "dimensionality." Typically, one should have a training set sample size to number of features ratio of more than 10:1 (each feature used in classification requires 10 samples) (Kanal et al, 1968). The absolute minimum is 3:1 (Foley, 1972). Purists would insist on a ratio of 50:1. The reason for such ratios is that many classification algorithms are based on an estimate of a multivariate probability density distribution. That estimate may be ill-defined if based on too small a sample. A **training set** and subsequent **test set** must be used for the selection of the "best" features, based on statistically significant differences in value for the two categories. This is similar to a hypothesis test. If features are selected because their values are different at the 95% confidence level ($p = 0.05$), and 100 features are tested, one can expect to find five features that are spuriously significant, i.e., will be effective at distinguishing the training set but not be effective for the test set.

TABLE 46-4 CLASSIFICATION RESULTS FOR A TRAINING SET OF CERVICAL CELLS

Actual Group	Predicted Group Membership						
	Unknown	1	2	3	4	5	6
1-INT	0.0%	99.0%	0.0%	0.0%	1.0%	0.0%	0.0%
2-IMMT	0.0%	0.0%	95.2%	0.0%	0.5%	0.0%	4.3%
3-DYSK	0.0%	0.0%	0.5%	96.7%	2.9%	0.0%	0.0%
4-DYSN	0.0%	0.0%	0.0%	3.7%	96.3%	0.0%	0.0%
5-DYSM	0.0%	0.0%	1.5%	0.0%	0.0%	95.6%	2.9%
6-CIS	0.0%	0.0%	1.4%	1.4%	0.0%	1.9%	95.2%

INT, intermediate cell; IMMT, immature metaplastic cell; DYSK, keratinized dysplastic cell, non-keratinized dysplastic cell; DYSM, dysplastic cell from an area of metaplasia; CIS, carcinoma in situ. These were the cyto-diagnostic designations used in the original TICAS project.

When data are sparse and a test set is not available, one may avoid this problem by applying a Bonferroni correction (Pagano et al, 2000), i.e., one sets a much stricter standard for accepting a feature as significant. In practice, this means that one selects only features that have a much higher confidence level, such as $p = 0.0021$. At this level of statistical significance, only 1 in 500 features tested could be expected to be spuriously significant. The selected features could be expected to adequately distinguish a training from the test set.

When more than two diagnostic categories have to be considered, a classification strategy must be chosen. There are two major choices. One may choose a **one-stage classifier** which makes diagnostic category assignment in one step (Lachenbruch, 1975). Or, one may elect to design a **hierarchic classifier** (Taylor et al, 1974, 1978; Breiman et al, 1983; Bartels et al, 1984) that makes a sequence of classification decisions.

In general, the hierarchic classifier strategy is superior. It creates a specifically formed classification rule for objects to be assigned to each category by creating a **consecutive series of decision nodes**. In a hierarchic classifier, a misrouted object can be retrieved at a subsequent decision node, which is not possible with a one-stage procedure. A hierarchic classifier is more labor intensive to develop. For the training of the second and subsequent decision nodes, only objects routed down to these nodes by preceding classification stages can be used. Consequently, one must have a large number of training samples. Table 46-4 presents the classification results for the training set of cervical cells in

P.1696

the TICAS project (Wied et al, 1968). Figure 46-21 shows such a hierarchic decision tree as derived for the classification of a test set of cervical cells. Hierarchic classification was used in a successful analysis of cells from the urinary sediment (Koss et al, 1983; Koss and Sherman, 1984). See Chapters 22 and 23.

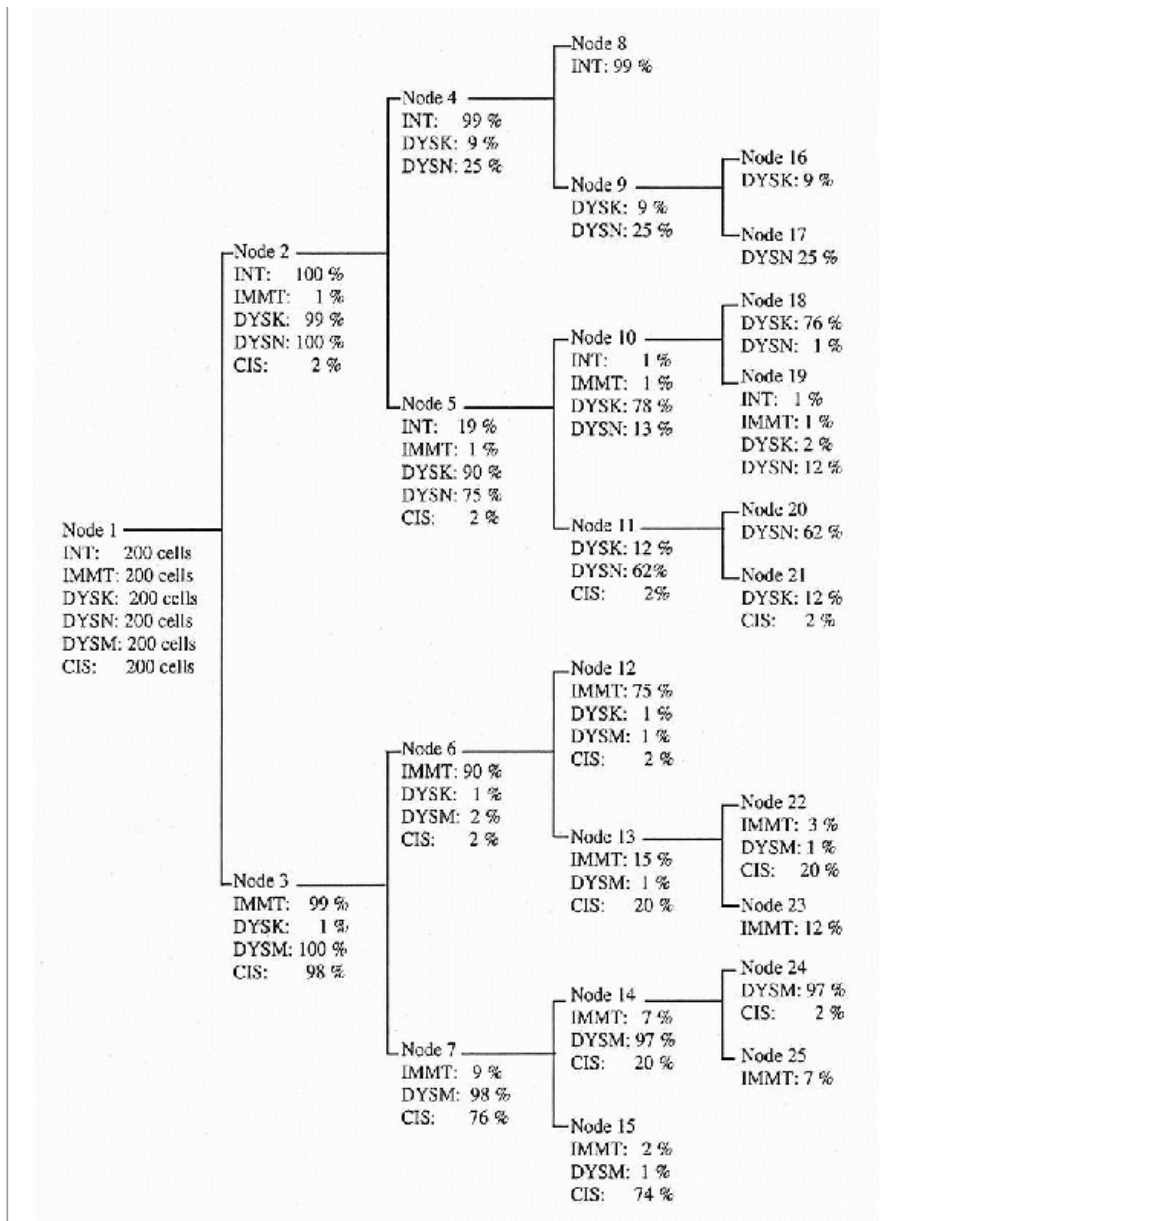

Figure 46-21 Classification tree for a test set of cervical cells derived in the course of the TICAS project (Wied et al, 1968). INT, intermediate cell; IMMT, immature metaplastic cell; DYSK, keratinizing dysplastic cell; DYSN, non-keratinizing dysplastic cell; DYSM, dysplastic cell from an area of metaplasia; CIS, carcinoma in situ cell. The cell diagnostic labels are the ones in use at that time.

Sampling methods and sample size criteria are of importance for all classification procedures. A random selection of objects (cells) is usually superior. Visual selection invariably introduces some bias. In many situations, cells reflecting a continuous progressive change are present and may be of different phenotype, following different progression pathways. Visual assessment may not clearly differentiate such cells or may not even detect their presence. One should always test a recorded data set for homogeneity. When the goal of the analysis is the derivation of a classification rule based on a mathematical/statistical algorithm, one should maintain an adequate training set sample size. For a two category discrimination based on typically 6 to 8 features, this would mean from 60 to 100 cells per training category and another comparable data set for test purposes. In a hierarchic classifier, the sample sizes required for

the training at the second and subsequent decision nodes are subject to the very same requirements.

In clinical applications, **patient to patient variability may be important** and the sample size requirements must be satisfied to meet epidemiologic standards. This becomes feasible only with full or partial automation of data acquisition and segmentation.

ARTIFICIAL NEURAL NETWORKS

An artificial neural network (ANN) is, in essence, a statistical classifier (Rumelhart et al, 1986; Grossberg, 1987; Anderson and Rosenfeld, 1988). ANNs can be operated in both a **supervised** or in an **unsupervised learning mode**. They can be trained to recognize and distinguish patterns. A neural network consists of an **input layer** where feature values are entered at each input node, and an **output layer** with nodes representing the alternate different outcomes. In addition, most neural networks have one or more **“hidden” layers**, inserted between the input and the output layers. Every input node is connected to every node in the next following hidden layer and every node in a hidden layer is connected to every node in the output layer, as shown in Figure 46-22.

The mode of operation of a neural network is straightforward. An input pattern is entered at the input layer. The

P.1697

signal from each node is fed forward through the network to the output nodes. For every pathway through the network that led an input signal to the correct output node, “weights” are increased, i.e., the network reinforces the signal routing. In pathways that lead to an incorrect output node, the signal weights may be reduced. This is done in small increments but the process results eventually in a high correct recognition rate. One of the frequently stressed advantages of an **ANN** is that **the network itself selects effective features and feature combinations**. The user, thus, does not have to make a feature selection before network training. Therefore, the user cannot introduce any bias by the feature selection.

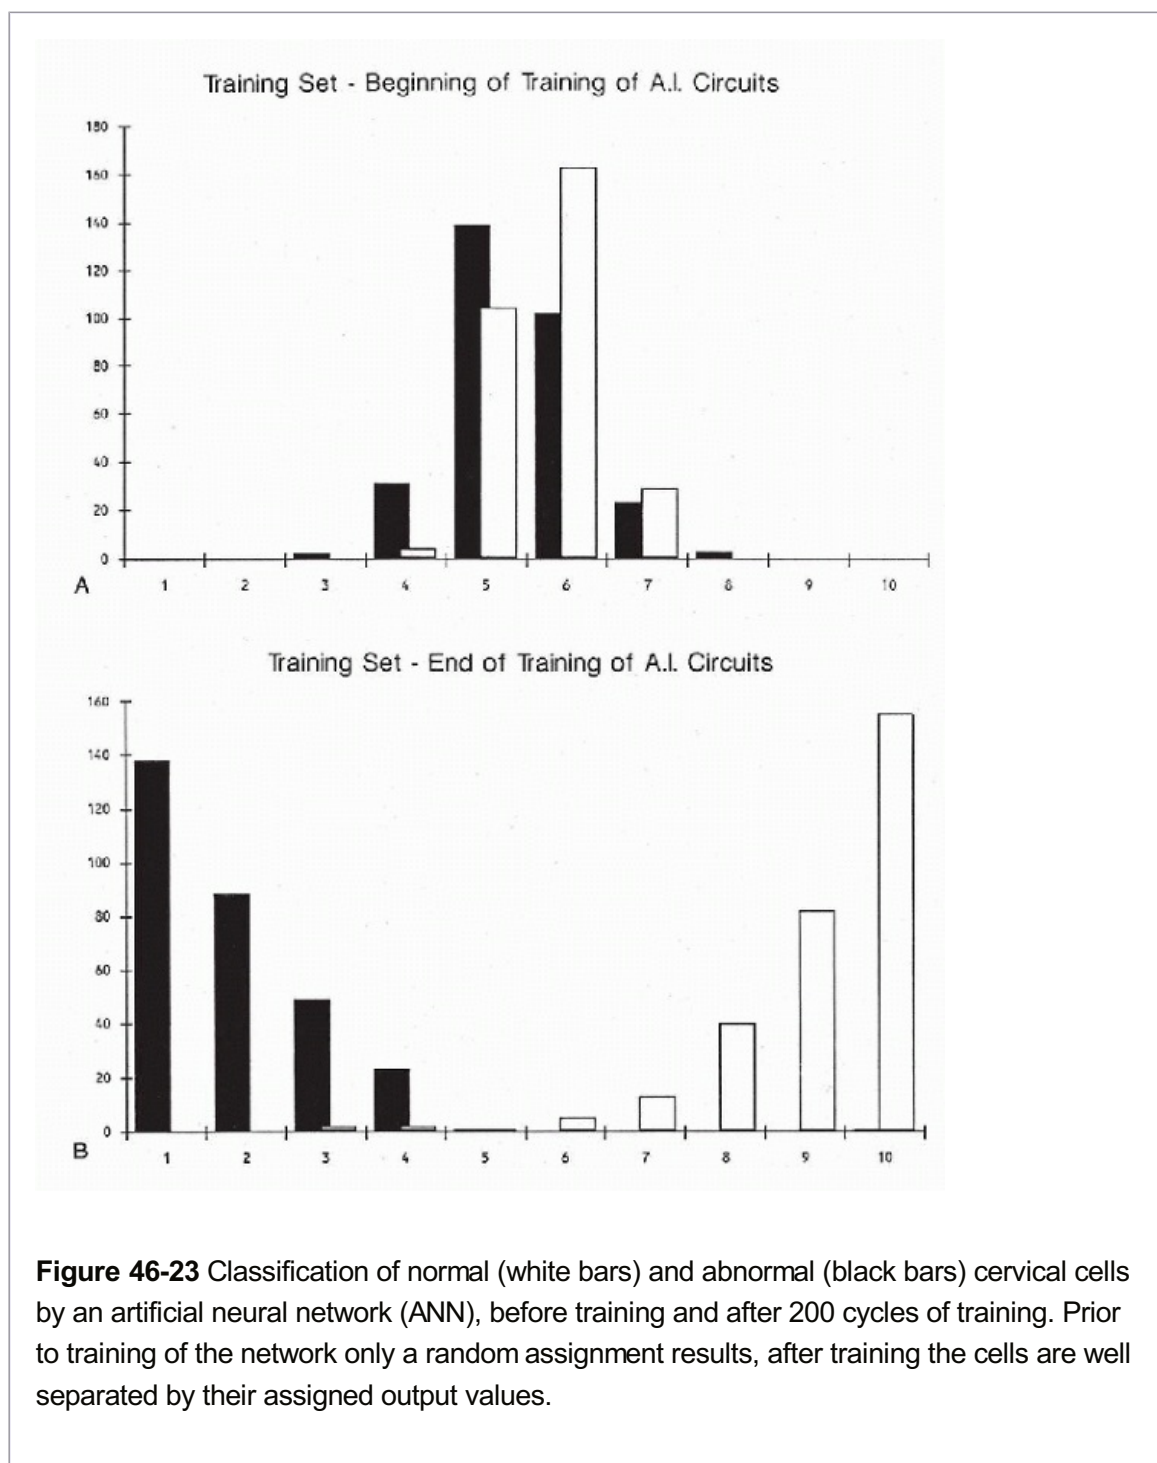

Figure 46-22 Basic structure of an artificial neural network. Information is entered via the processing elements of the input layer. Each element in that layer is connected to every processing element in the next “hidden” layer. There may be several hidden layers. The final output here is routed to a single processing element, as a numerical scaling from 1 to 10. It could also have been routed to a number of different output nodes.

The advantage of ANNs is that they can draw almost arbitrarily convoluted decision boundaries in a feature space. The designer, though, has to provide for a suitable number of nodes in the hidden layers. The ANN functions in the manner of a multidimensional polynomial classifier. The ANNs must be trained to achieve optimal performance. Figure 46-23 shows classification results for data from normal and malignant cervical cells. Initially, before training, the network classifies cells in a random fashion, after 200 cycles of training discrimination was achieved.

Figure 46-24 depicts the classification of a ploidy pattern by an ANN, shown as a Hinton diagram (Dytch et al, 1990, 1991). The ploidy pattern has 16 intervals, thus, there are 16 processing elements in the network's input layer. A hidden layer of eight processing elements was provided. The figure shows the accumulating weights from each processing element in the input layer, at each of the eight processing elements in the hidden layer. The dark boxes indicate positive values, the light boxes indicate negative weights; the size of the boxes indicate the magnitude of the weights. Finally, the weights from each of the eight processing elements in the hidden layer are fed to the three processing elements of the output layer, which represent

the diagnostic categories for which the network was trained.

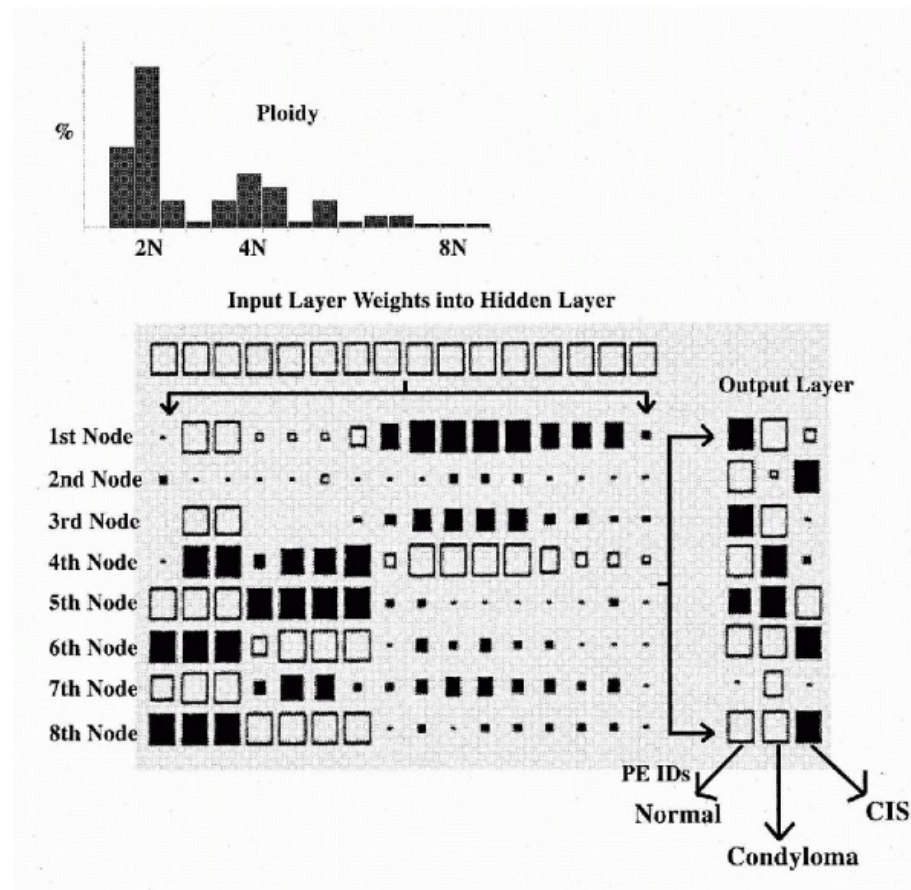

Figure 46-24 Classification of ploidy patterns by an artificial neural network (ANN). The ploidy pattern is divided into 16 intervals, so there are 16 input processing elements. A hidden layer of eight nodes was provided. The Hinton diagram shows positive weights as black, negative weights as white, the size of the boxes indicate the magnitude of the weights. Three output nodes are provided for the three diagnostic alternatives for which the ANN was trained.

The initial attraction of ANNs in diagnostic pathology was that one would not have to specify diagnostic clues or features. The network would, just like a pathologist in training, learn to recognize cells and tissues by itself. This is true in principle. In practice, this option was difficult to implement.

Two applications of ANNs in pattern recognition must be distinguished: **applications to an image**, and **applications to feature vectors**. In an application to an image, every pixel becomes a feature and the input layer must have as many nodes as there are pixels in the image. This is a problem of immense complexity, requiring a massive training effort. This holds for all but the most trivial recognition tasks, such as: Is this a large blob or not? In such problems, a pre-centered and pre-oriented binary pattern could be correctly recognized by sampling just a very few image pixels.

In an application to the grading of histopathologic **imagery of prostatic lesions**, Stotzka et al (1995) employed an already reduced image representation by using fields of 64×64 binary pixels. The training of a network capable of accepting such inputs took several weeks of continuous runs on a SUN SPARC 1 workstation (Sun Microsystems,

Menlo Park, CA). The system succeeded in distinguishing moderately from poorly differentiated carcinomas at a correct rate of 80% in the training set, and of 65% in the test set. However, this was practically the same recognition success as that obtained with standard statistical classification.

In an application to the **classification of multivariate data**, such as feature vectors, ANNs perform very well and require much less effort to train. Still, multivariate feature vectors representing cells or tissues rarely form highly convoluted distributions in feature space that would require such decision boundaries. One should examine, therefore, whether the effort to design and train an ANN results in a classifier performance that is significantly better than can be attained with well established multivariate statistical procedures.

Neural networks may well be of eminent value in data mining procedures where one has to search large volumes of high dimensional data for the existence of subsets. Such subsets must be assumed to form only "weak patterns" having escaped notice so far. Problems too complicated for a standard multivariate analysis (such as data sets represented by 50 to 200 variables) should still be tractable by neural network processing, in unsupervised learning mode.

A comprehensive review of the literature on applications of neural networks in cyto- and histopathology was given by Cross (1999). An ANN based apparatus, the PAPNET System, was approved by the Food and Drug Administration (USA) for screening of cervical smears (Koss et al, 1997). The machine is no longer manufactured (see below).

INFERENCE NETWORKS AND BAYESIAN BELIEF NETWORKS

In contrast to mathematical/statistical classifiers, both inference networks and automated reasoning systems operate in an open-ended manner designed to use as much of the diagnostic evidence as may be necessary to arrive at a particular outcome. An inference network allows one to accumulate diagnostic evidence and, in the process, to assess the certainty of a final diagnostic decision in numerical terms (Pearl, 1988; Bartels et al, 1992; Jensen, 1996). An inference network consists of a decision node, at which all alternate diagnostic categories are listed. This diagnostic **decision node** is connected to a number of **diagnostic evidence nodes**: one for each diagnostic clue with its possible outcome values. The connection is via a conditional probability matrix: it specifies what the probability for a given diagnostic alternate is, given that a certain outcome value for a clue has been observed. For example, given that the outcome for the clue "nuclear area" has been observed as "large," the probability that the diagnostic alternate "high grade precancerous lesion" applies may be 0.63. The conditional probabilities in the matrices for each clue are either estimated from a large sample or are derived from the experience of pathologists.

This part of the inference network is strictly probabilistic. As each of the diagnostic evidence nodes is polled, the probabilities for the different diagnostic alternates are updated. Finally, when the evidence collected from all the nodes is summarized, one diagnostic outcome has the highest probability.

The input into the diagnostic evidence nodes may be the numerical value of a measured feature, but it may also be a descriptive, fuzzy linguistic term. Therefore, the input layer of an inference network is based on possibility theory and fuzzy set theory. For example, the assessment of a diagnostic clue may be limited to the three outcomes: small, medium, or large. All of these are fuzzy, overlapping terms because they depend on the judgment of individual observers. One of these three possible outcomes is most accurate. However, because of the

overlap of all three membership functions, the other two outcomes cannot be fully discarded. In short, the diagnostic evidence input is, in this example, a 3-dimensional relative likelihood vector.

Thus, there are two levels at which uncertainty is managed. The first deals with the uncertainty of the diagnostic clue input. The second deals with the probability that a given clue may not be limited to a single diagnostic outcome. Inference networks allow a substantial number of diagnostic clues to be evaluated. Inference networks also provide a great deal of insight into the diagnostic process itself.

To help in assessing the extent to which a given diagnostic clue is expressed, **inference network systems** have been developed which offer a gallery of comparison imagery demonstrating the structure constituting the clue. The user does not estimate the likelihoods. Rather, a cursor is moved on the computer screen to the nearest match in the reference imagery and the system automatically assigns the correct relative likelihood ratio vector (Hamilton et al, 1996). Figure 46-25 shows an example of the accumulation of evidence in the assessment of a prostatic lesion as either low- or high-grade prostatic intraepithelial neoplastic (PIN) lesion. Nine diagnostic clues were evaluated. The cumulative belief for the outcome "low-grade PIN" was higher than that for the other diagnostic alternate.

Inference networks have been developed for a number of diagnostic tasks, the grading of prostatic lesions, diagnostic assessment of PIN lesions (Montironi et al, 1996), diagnostic assessment of aspiration smears in breast cytology (Anderson et al, 1997; Hamilton et al, 1994, 1995) and diagnostic assessment of melanoma (Stolz et al, 1993).

AUTOMATED REASONING SYSTEMS

Automated reasoning systems were developed to remedy a flaw in inference networks. The basic inference networks are vulnerable to exceptions in clue expression. For example, in a high-grade neoplastic lesion, one might expect to observe large nucleoli, but even though the sample clearly comes from such a lesion as suggested by all of the other clues, the nucleoli are not assessed as large. Such exceptions may lower the final probability of a correct diagnostic decision. Systems to be used in clinical practice must be able to handle such exceptions. Such systems must be provided with built-in knowledge that certain diagnostic clues may have multiple meanings, each of which should be considered by a different conditional probability matrix. When a clue expression is observed

P.1699

during the processing of the sample that is not in agreement with the remainder of expressions found for the entire clue set, a correction is automatically made and an alternate conditional probability matrix is used.

Figure 46-25 Belief curve resulting from the assessment of a sequence of diagnostic clues in the evaluation of a prostatic lesion. Of the two diagnostic alternatives, the belief reaches a higher value for the outcome of “low grade intraepithelial neoplastic lesion.”

A more advanced modification involves an information flow controller (Bartels et al, 1995), which monitors the accumulation of probabilities for a final diagnostic decision. When, in the sequence of clue evaluations, an exception or erroneous assessment has been observed, all prior assessments may be set aside, the system backtracks, and a corrected belief curve is formed. This prevents the impact of an error on the final diagnostic decision. Systems with this kind of capability come close to automated reasoning capabilities.

Inhomogeneous Training Sets

In most practical applications of image analysis to cytology, the randomly selected cells are not homogeneous. For example, a training set of nuclei from an atypical hyperplasia of the endometrium will contain several types of nuclei, even when sampling is done within a histologically clearly defined region of a lesion.

Nuclei randomly sampled in a region of colonic adenoma usually contain only a certain proportion of nuclei characteristic of this lesion. A sizable proportion of nuclei from histologically normal skin exhibit signs of solar-actinic damage (Bozzo et al, 1998). Under those circumstances, the processing sequence requires a **repetitive** or **iterative approach**.

First, a training set of supposedly “normal” nuclei and a training set of nuclei representing a lesion are formed. For these two sets of nuclei, a discriminant function is derived and its distribution is plotted for both training sets. The most representative normal and abnormal nuclei are formed into new training sets. A new set of features is selected and a new discriminant function is derived at first iteration. The classification rule is saved and applied to all nuclei recorded from normal skin. The distribution of new discriminant function scores sets a threshold for the existence of solar actinic damage. Seemingly normal cells expressing characteristics of progression to actinic keratosis may form only a very small subset that often escape notice during visual examination. This algorithm can be applied in assessing the efficacy of a chemopreventive intervention.

Unsupervised Learning

Unsupervised learning algorithms allow one to probe whether a data set is homogeneous or whether it contains subsets. There exist a large variety of unsupervised learning methodologies (Anderberg, 1973; Everitt, 1974; Hartigan, 1975; Jardine et al, 1971; McClellan, 1971; Romesberg, 1984). Unsupervised learning algorithms will, by design, partition a data set into different subsets, often as many as specified by the user. However, the partitioning may not

P.1700

produce statistically different subsets. Therefore, the significance of the subsets must be tested by a multivariate statistical significance test.

The choice of features is important. One may begin by arbitrarily choosing a set of usually effective features. For example, one might select features that discriminate between normal and highly abnormal cells. Often, supposedly homogeneous data sets (such as tumors of the same origin and diagnostic grade) contain cells that have markedly different feature distributions. One might then select two cases with the most pronounced difference to select features suitable for unsupervised learning. In any case, **feature selection for an unsupervised learning procedure is, at best, an educated guess**. By trial and error, other feature sets may be selected, but if no significant subsets are found, the data set is probably homogeneous. If subsets of nuclei with statistically significant differences are found, one can use these as tentative training sets and feature selection can take place by procedures used in supervised learning. This usually results in an effective feature set that can be submitted to the unsupervised learning algorithm.

A very effective unsupervised learning algorithm is the **P-index procedure** (McClellan, 1971). This algorithm starts by taking in the entire data set, where each cell is represented by the values of its several features. Next, it randomly generates two tentative cluster centers. Each cell is assigned to the cluster to which it is most similar in its feature values. For the two clusters thus formed, the centers are updated, which means that now some cells need to be re-assigned on the basis of similarity. The process continues until no re-assignments occur. For each cluster, the multivariate distribution is computed and a new cycle of reassignments is initiated.

When no more reassignments occur, the process is restarted, with an initial random generation of three start-up cluster centers. This cycle is repeated as many times as the user specifies. Finally, the Beale statistic (Beale, 1969) is computed to establish which partitioning of the entire data set provides statistically the best fit, and whether the subsets thus formed are statistically significantly different.

It is, at times, desirable to show the statistical significance of the formed subpopulations in a graphic mode. To visualize two statistically separated subsets, for example, in an 8-dimensional feature space, is difficult. In this case, one may process the eight features to form two linear combinations. Such a "Karhune-Loeve" expansion (Fukunaga, 1972) results in a projection of the data into a 2-dimensional display plane. Here, one can now show the clusters as bivariate distributions, with confidence ellipses for their bivariate mean values and tolerance ellipses for the data points representing the cells. Figure 46-26 shows an example. Nuclei from normal secretory endometrium form a homogeneous population. Nuclei from simple hyperplasia show two subpopulations, one very similar to normal cells, the other falling into the region of this display where highly abnormal nuclei are found. Nuclei from atypical hyperplasia also show two major subpopulations, both of which have feature correlations with highly abnormal cells. One of these two subpopulations falls into the region coinciding with the predominant subpopulation

of cells seen in adenocarcinoma.

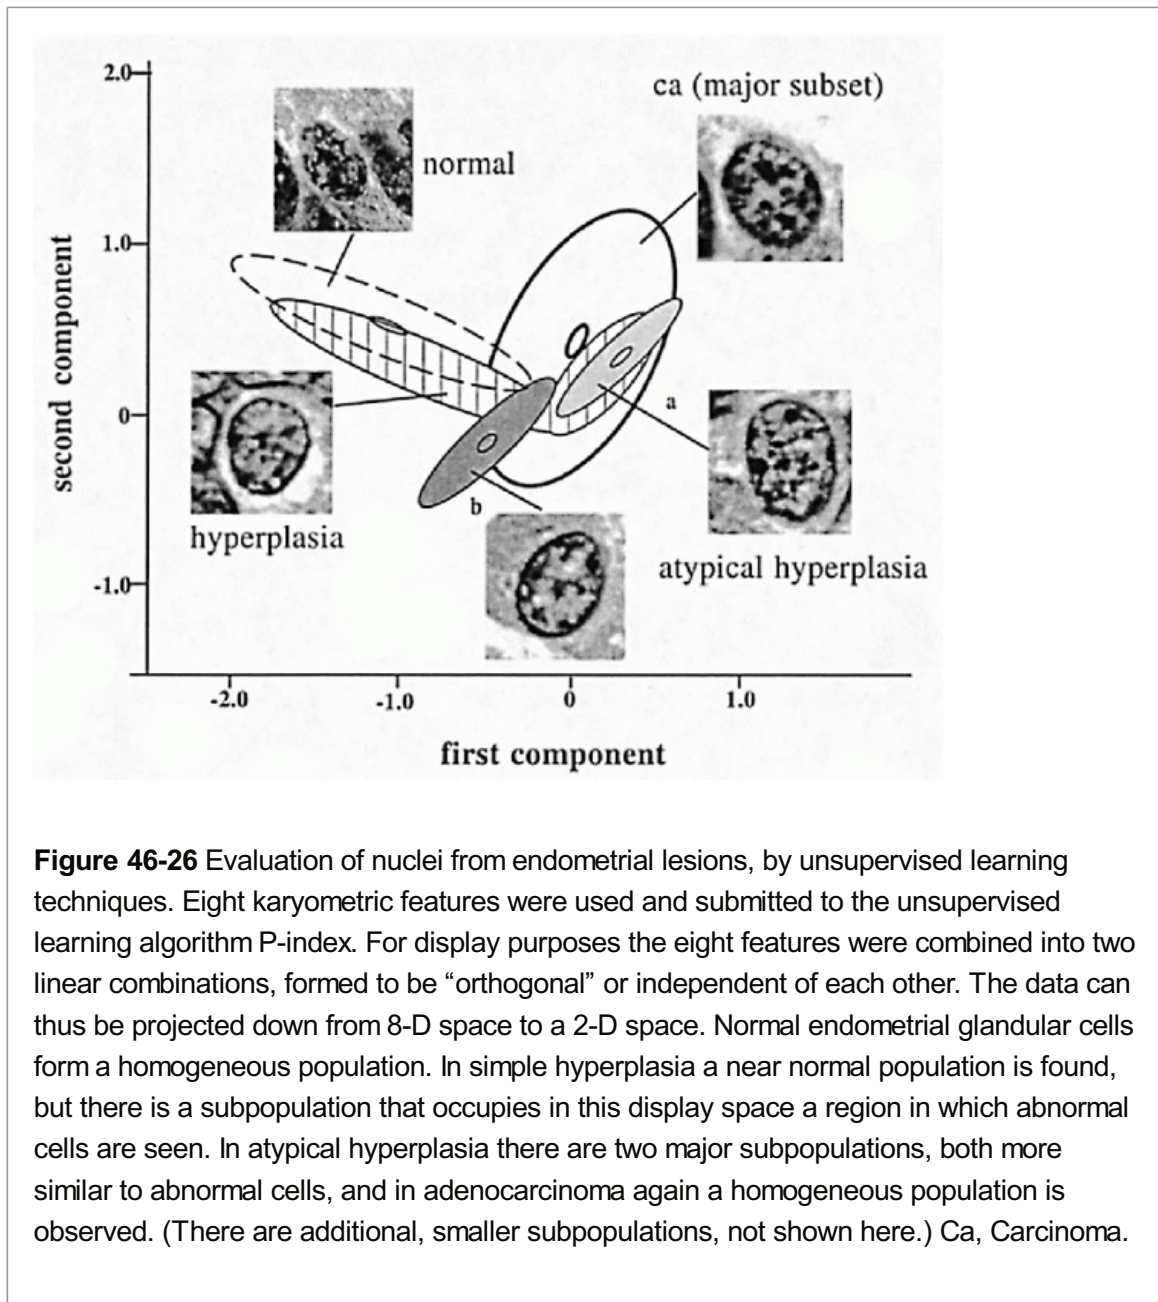

Figure 46-26 Evaluation of nuclei from endometrial lesions, by unsupervised learning techniques. Eight karyometric features were used and submitted to the unsupervised learning algorithm P-index. For display purposes the eight features were combined into two linear combinations, formed to be “orthogonal” or independent of each other. The data can thus be projected down from 8-D space to a 2-D space. Normal endometrial glandular cells form a homogeneous population. In simple hyperplasia a near normal population is found, but there is a subpopulation that occupies in this display space a region in which abnormal cells are seen. In atypical hyperplasia there are two major subpopulations, both more similar to abnormal cells, and in adenocarcinoma again a homogeneous population is observed. (There are additional, smaller subpopulations, not shown here.) Ca, Carcinoma.

Progression Curves for a Precancerous Lesion

Progression curves were first defined in the context of measurement of efficacy of a chemopreventive intervention. They were meant as a descriptive statistic to show the trend of changes in nuclei from precancerous lesions. While it is certainly possible that lesions of increasing abnormality develop along such a trend line, or progression curve, **the curve should not be interpreted as representing biologic behavior**. Lesions may never progress beyond a certain point or they may directly develop from very low abnormality to a high-grade cancer. The progression curve, though, does offer the capability to document statistically regression due to an intervention.

When the goal of the analysis is derivation of a progression curve of a lesion, the following processing steps are taken. A set of control, or “normal” nuclei and a set of nuclei representing the most advanced lesion are recorded. A discriminant function is derived, not to estimate a classification rate, but to define a useful direction in feature space for a progression curve. The

discriminant function is saved. Next, the average discriminant function score for data sets representing lesions of different levels of abnormality, from normal through low grade and high grade, are computed. The average discriminant function scores are plotted against grade. This is shown in Figure 46-27 for nuclei from colorectal

P.1701

tissue, recorded in normal rectal mucosa, in normal-appearing colonic mucosa far from an adenocarcinoma, mucosa adjacent to an adenocarcinoma, in adenoma, and in adenocarcinoma.

Similarly, a trend of progression can be shown for endometrial lesions (Bartels et al, 2000, 2001; Garcia et al, 2001), as seen in Figure 46-28. Figure 46-29 shows a progression curve for nuclei from prostatic intraepithelial neoplasia or PIN (Bartels et al, 1998). Note that nuclei measured in the visually normal epithelium, from prostates harboring either low- or high-grade PIN or adenocarcinoma, appear on the progression curve between normal epithelium and low-grade PIN. The intervals on the abscissa here are arbitrary. The marks for the diagnostic categories are arbitrarily equally spaced and are shown at sharply defined locations. In truth, they represent fuzzy membership functions that overlap widely along the abscissa. Therefore, any confidence limits or measures of variability for mean discriminant function scores, plotted above those grade location marks, are not really appropriate. The progression curve follows the estimated mean values. Within each grade, the different cases should be projected sideways

onto the progression curve. The measure of variability confounds random variability and variation due to progression.

Increased levels of abnormality or "progression" are better characterized by two independent criteria, such as a karyometric and a histometric measure. Bostwick and Brawer (1987) suggested that, in the progression of the prostatic PIN lesions, the basal cell layer becomes increasingly disrupted. This was used to define a progression curve for PIN lesions (Bartels et al, 1998). Figure 46-30 shows, along the abscissa, a binary representation of glands from PIN lesions, as provided by a machine vision system. The tissue was stained with hematoxylin and counterstained with an immunostain for cytokeratins. The feature extraction computed the number of gaps, gland perimeter length, proportion of gap length relative to gland perimeter, and gap size distribution. These features could be used as a measure of basal cell layer disruption. A measure of nuclear abnormality was used as ordinate (Bartels et al, 1999; Bartels et al, 2000).

Another choice for the abscissa is the relative risk for the development of invasive cancer. This is shown for a progression curve for preinvasive ductal carcinomas of the breast. Average nuclear abnormality is plotted here over a relative risk scale (Bartels et al, 2000) as shown in Figure 46-31. The nuclei had been recorded from tissue lesions of

P.1702

different architecture, such as cribriform ductal carcinoma in situ (DCIS), solid DCIS and comedo DCIS.

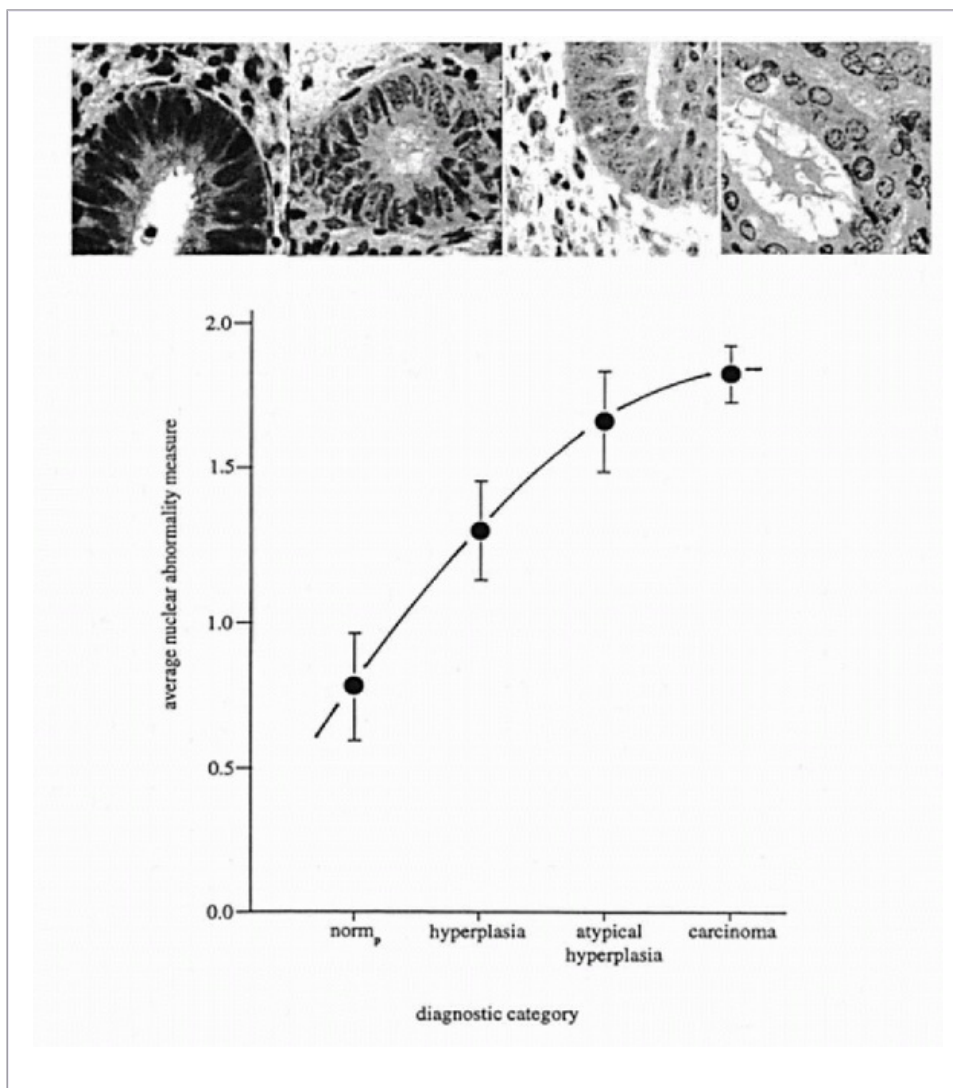

Figure 46-28 "Progression" curve for endometrial lesions.

A very informative plot is obtained when a discriminant function score, based on a small number of selected features, is plotted on the ordinate and a nuclear abnormality measure is plotted on the abscissa. For nuclear abnormality, all measured features are considered. This is shown for atypical hyperplasia of the endometrium and endometrial carcinoma in Figure 46-32.

The data from grades 1, 2, and 3 of endometrial carcinoma are tightly grouped. The data from atypical hyperplasia with co-existing adenocarcinoma (measured in the atypical hyperplasia component) can be shown to comprise three statistically different subpopulations of nuclei of varying degree of abnormality. Three subpopulations can also be shown to exist in the atypical hyperplasia lesions without co-existing adenocarcinoma, with the third subpopulation falling into the range of "normal" endometrial cells.

Figure 46-29 "Progression" curve for prostatic intraepithelial neoplastic lesions. Note the deviation from normal seen in nuclei from histologically normal appearing tissue of prostates harboring either a low- or high-grade PIN, or adenocarcinoma.

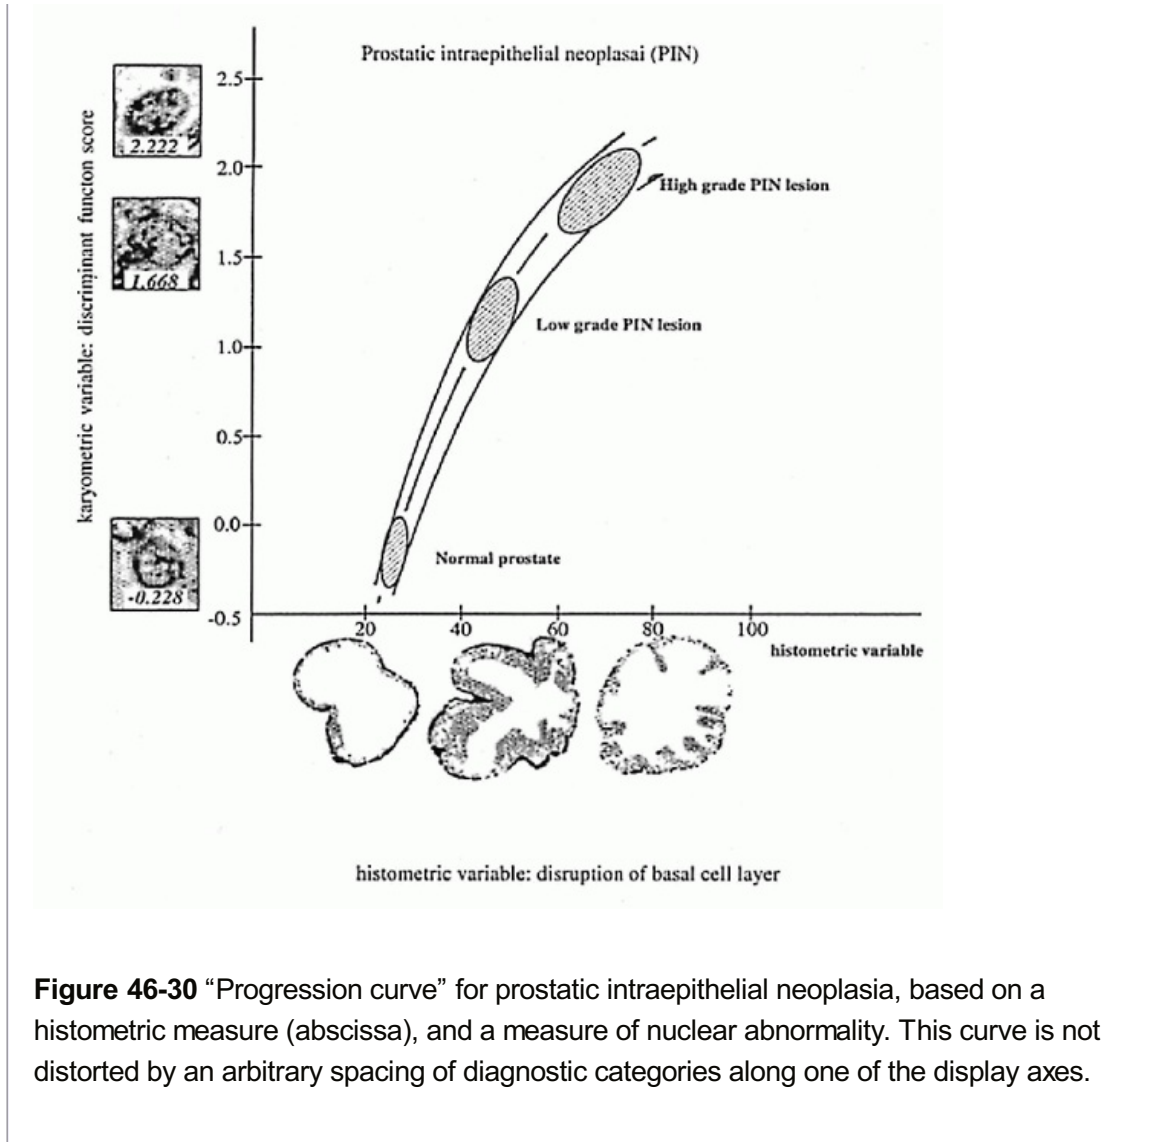

Figure 46-30 “Progression curve” for prostatic intraepithelial neoplasia, based on a histometric measure (abscissa), and a measure of nuclear abnormality. This curve is not distorted by an arbitrary spacing of diagnostic categories along one of the display axes.

A different situation arises when the cells exhibiting evidence of progressive change constitute only a small fraction of all cells, whereas most other cells are normal or near normal in appearance. One option is to assess the state of progression by computing some measure of deviation from

P.1703

normal for all cells in the sample, and to set a threshold for cells adjudged to be “not normal.” The proportion of those cells is plotted on the ordinate. For a certain fraction of these cells, e.g., the 10% with the highest deviations from normal, an average measure of abnormality is computed to serve as abscissa. Such a progression curve is shown for solar keratotic lesions in Figure 46-33. Here, the averaged discriminant function score for the 10% most deviating cells was computed (Bozzo et al, 2001).

Figure 46-31 Mean nuclear abnormality for nuclei from preinvasive breast ductal lesions, plotted as a function of relative risk for the development of infiltrating disease.

Figure 46-32 "Progression" curve for subpopulations of nuclei in premalignant and malignant lesions of the endometrium. In atypical hyperplasia three distinct subpopulations are seen, in cases with co-existing adenocarcinoma and in cases where no adenocarcinoma was documented. In the latter cases, the subpopulations have a lower nuclear abnormality, the third subpopulation falls in its nuclear abnormality values into the near normal range. Ca, carcinoma.

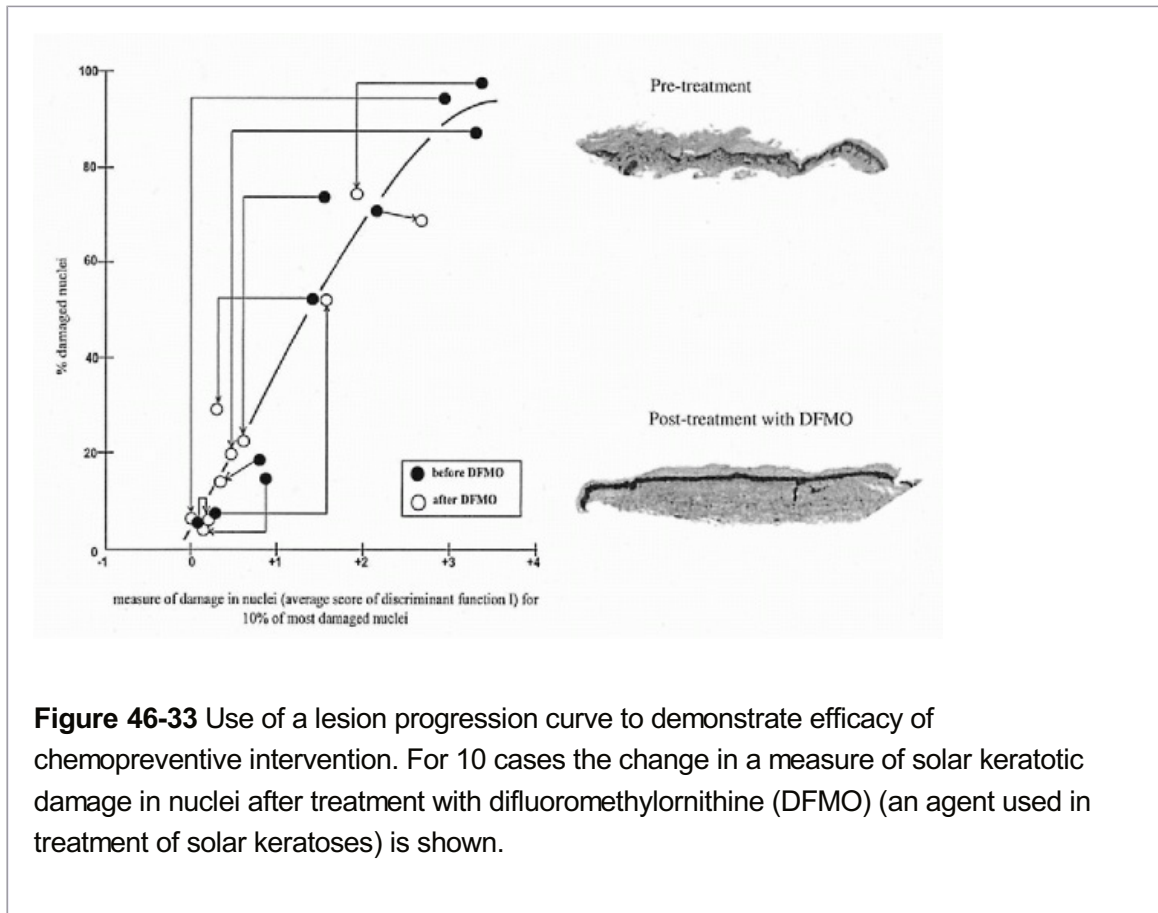

Figure 46-33 Use of a lesion progression curve to demonstrate efficacy of chemopreventive intervention. For 10 cases the change in a measure of solar keratotic damage in nuclei after treatment with difluoromethylornithine (DFMO) (an agent used in treatment of solar keratoses) is shown.

AUTOMATION OF PRIMARY SCREENING FOR CERVICAL CANCER

Efforts to automate the tedious process of primary screening of smears for cervical cancer go back for 40 years to the "Cytoanalyzer" (Tolles et al, 1956). This machine was based entirely on analog signal processing, with a flying spot scanner. Given the state of technology at the time, it was a most remarkable accomplishment. However, the designers had greatly underestimated the complexity of the problem; for instance, the device could not deal with clusters of leukocytes

P.1704

and also would declare a sample as "normal" if it contained no cells at all.

There followed the development of a number of experimental systems, such as the CYBEST system (Tanaka et al, 1973, 1977A, B, C, D, E), the TUDAB system (Burger, 1976; Abmayr et al, 1979), the BIOPEPR system (Zahniser, 1979), CERVIFIP 1987 (Tucker et al, 1983), FAZYTAN (Reinhardt et al, 1982), and LEYTAS (Ploem et al, 1987).

The foundation for machine recognition of cervical cells had been well established (Wied et al, 1976; Pressman et al, 1979; Grohs et al, 1994). However, to accomplish correct cell recognition rates on material prepared, not under rigid laboratory conditions, but in a clinical setting, proved difficult at that time.

Technologically, **an automated screening system poses a formidable challenge.**

Screening an entire slide at a sampling density that provides an adequate number of pixels so that moderate changes in nuclear size and the structure of nuclear chromatin can be reliably characterized involves the recording of several gigabytes of data. The data reduction task is enormous—from several gigabytes of photometric data to a few bits of information defining the

diagnosis of a slide—a ratio of about 1 billion to 1; this must be done without loss of diagnostic accuracy.

Primary screening is a search for possibly rare events. To assure, with high probability, the detection of a very small proportion of abnormal cells, a very large sample size must be examined, probably not less than 50,000 to 100,000 cells (Bartels et al, 1976). Unfortunately, economizing strategies, such as sampling only of a smaller number of representative fields, cannot be employed, since the abnormal cells are not randomly distributed on the slide.

The discovery of the MAC (malignancy associated change) in cervical squamous cells raised hopes that the search for rare events could be replaced by measurements of abundantly available intermediate squamous cells. The MAC effects, though, are subtle and possibly not robust enough to allow reliable detection.

Economic considerations suggest that an automated screening device should process a slide within 3 to 5 minutes. The required read-out rates of 100 MHz and more have only very recently become possible.

A point spread function, adequate to resolve fine detail, is only offered by high numerical aperture objectives. Such objectives provide only a limited field of view. This, in turn, implies very time consuming multiple steps and repeat field data acquisitions.

All of these problems notwithstanding, two commercial systems for the screening of cervical smears were approved by the US Food and Drug Administration: AutoPap (Tri-Path Imaging, Inc, Burlington, NC) for automated scanning of low-risk smears, and PAPNET (Neuromedical Systems Inc, Suffern, NY). The latter is no longer being manufactured because of bankruptcy of the company. Both devices performed rather well by providing clinically useful data.

The automated screening for cervical cancer brings up a fundamental problem. A slide that is processed by an automated device and assessed as “normal” is not going to be reviewed. It is clear that the machine has made a diagnostic decision. It is a decision that, until now, has been the responsibility of a trained professional with long term experience. Although an automated device can be entrusted with this task under well-defined conditions, the process of how a system arrives at a diagnostic decision deserves very careful consideration (Bartels et al, 1998; Bartels, 2000).

This problem is partially resolved in devices that operate essentially in a “**dry enrichment**” mode. The automated device finds objects that potentially might be abnormal cells and presents their images to a cytologist, who renders a diagnostic decision. This principle was incorporated into the PAPNET system. Most recently, a similar device, ThinPrep Imaging System (Cytoc Corp., Boxborough, MA), has been introduced as a semi-automated cell imaging system to facilitate screening. The system is based on a proprietary nuclear stain and computer scanning. This approach avoids many of the difficulties of a fully automated device, although, even here, the system relies on the ability of an automated module to detect objects for presentation to visual review with great reliability.

In reference to **organs other than the cervix**, the PAPNET system performed rather well on cell samples of **sputum** (Hode et al, 1996) and **esophagus** Koss, et al, 1998).

METHODS

Image Data Acquisition: Videophotometry

Images are almost exclusively recorded on videophotometers (Bartels et al, 1994). A

videophotometer consists of a research microscope with a computer controlled precision stage, a highly stabilized light source, a CCD type videocamera, a frame grabber, and a computer. An important, and often not mentioned, component is an image acquisition software package that includes a comprehensive calibration procedure.

Optics

For karyometry, **oil immersion objectives** are the rule. A typical example is a 63:1, numerical aperture (NA) 1.40, flat field type of objective. In histometry, a preferred choice is a 20:1 NA 0.75 flat field objective.

Images in karyometry are usually recorded at 4 to 6 pixels per micron and in histometry at 2 pixels per micron. This represents some oversampling to allow for the loss in band width, image sampling at the CCD video camera (see below), and signal transduction to the frame grabber.

The **image sampling rates** are adjustable by the relay optics, by the choice of focal length for the projective that projects the image directly onto the face of a CCD, or by a pancratic projective, i.e., a zoom system. One may compute the effective sampling rate at the face of the vidicon (Bartels and Thompson, 1994), or one may project an object micrometer onto the videoscreen and measure it directly.

A well corrected **condenser**, preferably an aplanatic-achromatic system, is essential. One may also use a 16:1 NA

P.1705

0.40 plan-apochromatic objective mounted invertedly, as a condenser for karyometric work.

There is a trade-off to be considered between photometric accuracy and spatial resolution. For emphasis on accurate microphotometry, the condenser aperture should not exceed 0.30 in order to limit the deviation from a strictly parallel beam path. However, when micromorphometry and chromatin texture are of prime interest, one may choose a larger aperture on the condenser side so that the sacrifice in lateral resolution is not so severe. Whatever the chosen setting, it is absolutely essential to keep the condenser aperture iris fixed for all measurements. Any resetting might affect the contrast transfer function of the system. It is best, in fact, to lock the aperture stop control.

For most **image analytic tasks** strictly stoichiometric staining and highly linear photometry is not absolutely necessary. Good reproducibility, though, is essential. A videophotometer is not, in principle, ideally suited as a photometric device. Videophotometry is based on image scanning, i.e., the entire image is illuminated at the same time. Thus, stray light from all object points may fall onto the detector element recording the OD value for a given pixel. For this reason, one can rarely assume a precision of better than 1%, i.e., of approximately 7 bits. Stray light errors of this nature are not amenable to ordinary correction measures since they depend on how many objects are in the field of view and how much each object scatters to contribute to stray light at a given pixel.

The choice of a **video camera** requires careful consideration. Most cameras now are of the CCD type. It is preferable to have a camera with elements equidistantly spaced in x and y direction, and to have square pixels. Cameras with very large CCD arrays often have a number of nonfunctioning sensor elements. The camera should have adequate sensitivity so that a response of 255 light values can be reached using an oil immersion objective with a narrow bandpass spectral filter in place. Particularly in digital cameras, one might want to test sensitivity to be sure one can indeed obtain a full 8 bit of photometric resolution. It must be

possible to shut off the automatic gain control. The camera should provide separate red-green-blue (RGB) output, and not just a composite signal. In color CCD cameras, one should determine the positions of the spectral bands. It is highly desirable for the camera to have separate gain controls for the RGB channels, and separate black level adjustments. This adjustment is done first, since it affects signal level. In a three chip CCD camera without separate gain adjustments, one would adjust saturation for the camera's most sensitive channel and accept, without changes, the gain in the other two channels. In all gain adjustments, it is preferable to adjust the light source and to keep the camera gain to a minimum to reduce the noise level. A pixel noise of 3% is not unusual.

Data acquisition software, therefore, usually averages 4 to 8 frames before storing the image to reduce pixel noise. Some frame grabbers provide black level and gain adjustments as well. The final settings, thus, are always an iterative process. It is advisable to establish beforehand whether a given camera is compatible with a given frame grabber and whether a given frame grabber will work with a particular computer.

A further consideration is the “**fill factor**” of the CCD camera. In many CCDs, the light sensitive elements are small and the space among them is occupied by circuitry. Small structures may be imaged onto an obscured area. The effect can be differences in feature values for the same object when moved laterally under the microscope, and then rerecorded.

Digital cameras frequently pose a problem with focusing the microscope. Under oil immersion, it is very difficult to focus when the camera is providing only 12 frames per minute. One might need a separate real time output from the digital camera for focusing.

The **light source** should be regulated to millivolt accuracy. When an oil immersion objective is used with a contrast filter, the source is usually run close to its maximum voltage in order to provide adequate illumination. Even very small voltage fluctuations may lead to differences of several light intensity values, since under those conditions, the radiance of the source changes steeply with the voltage. Adjusting the light source leads to a change in the source color temperature: increased voltage makes the light emission in the blue range higher, but the red end of the emission spectrum may increase even more. In adjusting the source in an attempt to reach saturation for the blue channel, the red channel may become over illuminated. It is best to insert a **blue filter** of the type that is used to adjust the color temperature of a tungsten source to the spectral sensitivity of daylight film. By choosing a filter with appropriate characteristics and adjusting the source, one can attain correct illumination levels for both the red and the blue channels. **Rigorous calibration is an absolute prerequisite for reproducible results.** It involves the following steps.

The microscope is set up for **Koehler illumination**, i.e., the objective is focused on the specimen, and the condenser is focused so that the field iris is in focus together with the specimen. The condenser should be centered and the field iris opened so that it just disappears at the edge of the field of view. In most microscopes, the aperture stop is then also appropriately focused. The aperture stop should be fixed. Even a small adjustment can significantly alter the photometric response. Ideally, the aperture stop should be locked. An empty object area is moved under the objective. The source is adjusted until the **camera response histogram** reaches light intensity values in the 200-250 value range. No pixel value should exceed that level as seen in Figure 46-34. The intensity value histogram should be unimodal and sharply peaked.

Response linearity is established as the next step. This is done by introducing neutral density

filters of known optical density. To establish a full transmission value (or zero optical density), a fully transparent thin glass plate is inserted into the beam path, to allow consideration of the reflection losses incurred during insertion of the neutral density filters. This plate is then removed and a sequence of independently calibrated optical density filters is inserted. For each, the camera response is recorded, for instance for a sequence such as OD 0.10, 0.20, 0.40, 0.60, 0.80, 1.00, 1.20, and

P.1706

1.6. These values form the calibration curve relating observed camera responses to true OD values as shown in Figure 46-35. The software establishes a look-up table for later conversion of all pixel light intensity values to optical density. The clear glass plate is inserted again.

Figure 46-34 Demonstration of camera set-up. The illumination is adjusted so that no pixel value exceeds the value of 255. The distribution of pixel light intensity values should be unimodal and sharply peaked.

Background correction is the next step. An empty field is recorded and stored. The stage is moved to several other locations with empty fields. All these images are averaged. This serves to eliminate small imperfections on the slide. The averaged clear background mask is stored. It allows consideration of any unevenness of illumination and it establishes 100% transmission for every pixel. It is essential that every time the light source is re-centered or refocused, the condenser is refocused or re-centered or, what should be avoided, the aperture stop is reset, the background correction mask be re-established. Some commercial systems offer a "life-time calibration" built in, and without software to conduct an independent check or recalibration. This is an undesirable procedure.

Figure 46-35 Calibration curve for light intensity values to optical density values, measured to establish a look-up table.

CONCLUSIONS

Quantitative measurements in cytopathology and histopathology have been shown to provide insight into the sequence of events in the development of disease. They can reveal subtle differences in cells and tissues too inconspicuous to be noticed by visual inspection. The statistical and spatial distribution of the nuclear chromatin, in particular, has been shown to provide a reliable indication of the metabolic state of a cell and to reflect early phenotypic changes.

Mathematical analytic and multivariate statistical procedures have provided practical tools to extract objective data which eventually may form the basis for numerically defined diagnostic standards.

Quantification can be expected to become a valuable adjunct to existing cyto- and histopathologic diagnostic procedures, as is the case already with specific applications. One should not expect a diagnostic assessment of a clinical sample by an objective, but essentially automated process to result in a sophisticated interpretation at par with an experienced professional. However, just because of the variability of professional experience and its individual uniqueness, visual diagnostic assessment is subjective. There is much inter-observer disagreement in diagnostic assessment of cells and tissues, as repeatedly stressed in this book. The information technology offers image data bases, digital image displays, reference data, and numeric comparisons that could greatly reduce the inter-observer variability. There is the potential for technology to provide advanced diagnostic expertise in situations where human resources with comparable knowledge are just not available.

Quantification and numeric data allow a highly specific characterization of nuclei, cells and tissues. This capability may permit proper consideration of the diversity in pathologic processes. Variability in numeric data in diagnostic pathology must be attributed to at least three different causes: true random variability, variability within a given diagnostic category or grade due to progression, and variability caused by true diversity.

This can be overcome, to some extent, by numerical analysis and a very specific characterization of lesions. Numerical analysis may also serve to identify diversity of nuclei of different phenotypes, to follow different pathways of progression, or to identify neoplasms with different relative risk for progression to invasive cancer.

Flow Cytometry

Myron R. Melamed

HISTORICAL OVERVIEW

Cytometry is the science of cell classification and analysis based on cell measurements. It represents an effort not only to quantify by objective measures the diagnostic cell features that are interpreted subjectively by the human microscopist, but also to quantify constituents and functional attributes of the cell that may not be apparent by light microscopy and, nevertheless, play an important role in defining the cell or its functional state. **By flow cytometry, we mean the technique of measuring cells in suspension as they flow in single file through a measuring sensor.** It has a number of advantages, among them the ability to measure large numbers of cells individually in a few seconds, to make and record several different measurements simultaneously on each cell, and to control staining conditions precisely and equally for all cells.

The beginnings of cytometry are properly attributed to Torbjørn Caspersson (1940, 1950), who first demonstrated that nucleic acid content and protein in the unstained cell could be quantified by measuring absorption of light in the ultraviolet and visible spectrum, respectively. Both measurements varied depending on cell function and were increased in cancer cells.*

In a later microspectrophotometric study, Leuchtenberger et al (1954) confirmed the increased DNA content of cells from malignant, compared with benign, human tissues. At the same time, Mellors, with Keane and Papanicolaou (1952), demonstrated that **dysplastic and cancer cells in cervical cytology slides had increased nucleic acid content**, and suggested that this might be the basis for automated examinations of the cytology slide (Table 47-1).

Friedman (1950) and Mellors and Silver (1951) introduced fluorescent nucleic acid dyes to gynecologic cytology. Ruch (1966) later provided the physical basis for the more precise DNA measurements obtained by fluorescent Feulgen

P.1710

and other fluorescent DNA stains compared to what was possible with absorbing dyes.

TABLE 47-1 ABSORPTION MEASUREMENTS OF UTERINE CERVICAL SQUAMOUS CELLS	
Papanicolaou Cytology Class	Absorption (Arbitrary Units) 260 mμ
I, II (benign squamous cells)	0.24 ± 0.10

I, II (benign parabasal cells)	0.33 ± 0.15^a
III (dysplasia/suspicious)	0.51 ± 0.22^a
IV, V (malignant)	0.54 ± 0.23^a

^a Significant difference.

After Mellors R, Keane JF, Papanicolaou GN. Nucleic acid content of the squamous cancer cell. Science 116:265-269, 1952.

The concept of counting and later measuring cells in suspension as they flowed through a measuring station reached first practical application with the Coulter Counter in the mid-1950s. This instrument recorded a change in electrical potential as each of the individual cells in salt solution passed between electrodes in an electrical field (Fig. 47-1) (Kachel, 1990). Until **the invention of multiparameter flow cytometry by Kametsky et al in 1965**, however, there was no way to make photometric measurements of cells in flow as had been made on glass slides. Kametsky et al (1963) had confirmed Mellors' work by scanning benign, dysplastic and malignant uterine cervical squamous cells on slides and demonstrating increased absorption of neoplastic cells at dual wavelength measurements optimum for nucleic acids and for proteins (Fig. 47-2). While this suggested a possible means of screening for precancerous lesions of the uterine cervix, the process of scanning cells on slides was then much too slow for practical clinical application. High-intensity laser light sources and modern era computers were not available at that time. In addition, there were enormous technical difficulties with background noise, maintaining focus, discriminating and analyzing individual cells, and separating reactive from neoplastic cells. On the other hand, **the flow cytometer could carry out simultaneous measurements of two or more features on each of several thousand cells in a few seconds**. It had other advantages, as well, that included separation and ready discrimination of single cells, greater uniformity of staining for the cells in suspension, and better precision of measurements including measurements of DNA.

Figure 47-1 Diagrammatic representation of Coulter counter flow chamber. Cells in suspension are made to flow from one chamber into the other through a small orifice. The electrical signal generated by each cell is recorded as it traverses the orifice, providing a cell count and also an indicator of cell size. (From Kachel V. *In* Melamed MR, Mullaney PF, Mendelsohn ML (eds). *Flow Cytometry and Sorting*. New York, Wiley, 1979.)

There was strong motivation at that time to develop an automated instrument for cervical cytology screening and grants for that purpose from government and industry funded much of the early research and development (see Melamed, 2001, for a historical review). A clinical trial to screen cervical cytology specimens with a prototype flow cytometer built by Kametsky was reported by Koenig et al (1968) who examined specimens from 1,155 high-risk patients. Only 45% of cervical cytology samples were adequately cellular; of these, the instrument selected a very large proportion, namely 35%, as abnormal. Although the selected samples included 85% of the proven positive cases, the results were not good enough for a clinical instrument. There were no further trials of flow cytometry for cervical cancer detection in the United States.

In Kametsky's flow cytometer, cell flow was perpendicular (i.e., orthogonal) to the direction of the excitation beam of light (Fig. 47-3). In an instrument developed independently at almost the same time by Dittrich and Göhde (1969) in Germany, cell flow was parallel (i.e., colinear) with the excitation beam (Fig. 47-4). Very precise measurements could be obtained as the cells passed through the focal plane of the beam, with coefficients of variation (CVs) below 2%. Göhde and Dittrich (1970) also were the first to make use of energy transfer between the fluorescent dyes ethidium bromide and mithramycin to achieve high intensity fluorescence staining of DNA in cervical cytology samples. They reported successfully detecting the neoplastic cells in clinical cervical cytology samples (Göhde et al, 1972).

Since its invention over 40 years ago, flow cytometry instruments have been extensively modified and improved and many new techniques of specimen preparation and staining have been designed specifically for these measurements (see below and appendix to this chapter).

The very sophisticated, computer-interfaced flow cytometers available today are capable of six or more simultaneous measurements on each of the thousands of cells in a sample, with analysis and graphic presentation of the data within a few minutes. Many biochemical, physiologic, and molecular cell features now may be quantified by flow cytometry (Table 47-2). **There are two important clinical applications: (1) measuring DNA content of tumor cells to distinguish diploid from aneuploid tumors and display tumor cell cycle distribution (i.e., proliferative activity), and (2) diagnosis and classification of leukemias and lymphomas by expression of cellular antigens.** Thus, although the original objective of automatically screening cervical cytology specimens was never achieved, flow cytometry has become an essential research and clinical laboratory instrument with many other applications.

P.1711

Figure 47-2 Absorption patterns of three cells from a cervical smear at different wavelengths. Scanning at 2,652 Å corresponds to absorption by nucleic acids, scanning at 2,976 Å corresponds to absorption by certain other proteins, scanning at 5,460 Å corresponds to visible light. The cell on the left is a normal squamous cell, whereas the cells designated as *A* and *B* represent varying degrees of abnormality. Cell *A* is dyskaryotic, closely resembling the benign cell on the left, except for an enlarged and hyperchromatic nucleus. Yet its absorption pattern in ultraviolet light (2,652 Å) reveals a marked increase in the cellular content of nucleic acids. In cell *B*, which is a frank squamous cancer cell, there is a further increase of the cellular nucleic acids to the point of partial obliteration of the nuclear peak. (Modified from Kametsky LA, et al. Ultraviolet absorption of epidermoid cancer cells. *Science* 142:1580-1583, 1963.)

Figure 47-3 *A*. Schematic representation of an orthogonal flow cytometer. The cells in suspension are injected in single file into a fluid stream that aligns them in the center of a quartz glass channel. The channel measures 100 μm in diameter, large enough to avoid clogging. As each cell passes through the focused beam of laser light, it excites a fluorescence flash that is collected, quantified by a photomultiplier, and recorded by computer for graphic display and analysis in "list" mode. The more sophisticated research instruments have two additional laser excitation beams increasing the number of measurements made on each cell. Light scatter signals give information on cell size and texture. *B*. Diagram showing laminar flow injection of cells into a fast moving stream of sheath fluid that orients asymmetrically-shaped cells and centers them in the flow channel. The flow may be up or down.

P.1712

Figure 47-4 Diagram of Göhde's colinear flow cytometer. Cells flow along the vertical optical axis. Peak fluorescence is measured as the cells pass through the focal point of the beam, after which they are washed to the side and away by another stream of fluid. (From Göhde W, et al. *In* Melamed MR, Mullaney PF, Mendelsohn ML (eds). *Flow Cytometry and Sorting*, New York, Wiley, 1979.)

PRINCIPLES

Photometric measurements are carried out on cells in suspension, flowing one at a time in a single file at a very rapid rate through a measuring beam of light. In Kamensky's original instrument, light absorption by the cell was measured at two different wavelengths in a flow channel orthogonal (perpendicular) to the incident beam of light. He and others soon turned to **measurements of fluorescence**, which had the advantage of measuring light emitted against a dark background, and is much more sensitive and more precise than measurements of absorption (Dittrich and Göhde, 1969; Hulett et al, 1969; Kamensky and Melamed, 1969; Van Dilla et al, 1969). For appropriately stained cells, there is a linear relationship between the fluorescence intensity and the amount of fluorophore (i.e., fluorescent dye) bound to a particular cellular constituent. The measurements are accurate because most cells have very low intrinsic fluorescence at the wavelengths measured. In contrast, the relationship between signal and cell constituent for absorbing dyes is logarithmic and high resolution scanning is necessary to reduce the distributional error of particulate and uneven staining.

There are many fluorescent DNA and protein stains available and a growing number of monoclonal and polyclonal antibodies to specific cellular components that can be tagged with fluorescent markers. It is possible to stain and measure three or more different cellular constituents simultaneously, using several fluorescent dyes with different emission spectra

excited by a single laser. With dual or triple laser instruments, suggested long ago by Shapiro (1983), dyes with different excitation wavelengths can be used, permitting simultaneous measurements of even more cellular

P.1713

constituents. A method for six-color, dual laser immunophenotyping of leukocytes by laser scanning cytometry (see below) was described by Gerstner et al (2002).

Light Sources

Most commercial flow cytometers use an **Argon ion laser**, which emits a narrowly focused (~5 μm) beam of near UV monochromatic blue light (488 nm). It is a very stable light source. The most useful fluorescent dyes have excitation maxima near this wavelength (see below). The red **heliumneon laser** (633 nm) is becoming more common as a second excitation source, and new fluorescent dyes have been designed for excitation at this wavelength (Mujumdar et al, 1993). The **krypton and helium-cadmium lasers** (325 nm), which have been used for excitation in the ultraviolet, are expensive and unstable and will probably be replaced by inexpensive violet diodes (400 nm) that are now available. Excellent instruments, made primarily in Europe, use **mercury arc** or **halogen lamps** for excitation.

Laminar Flow

One of the problems encountered with the earliest flow cytometers was clogging of flow channels, made narrow enough to keep the cells in single file, and centered as they passed through the focus of the laser light beam. If the channel is too narrow, it may be obstructed by a single large cell or by small groups of cells that were not adequately dissociated. If the channel is very wide, the cells will wander off center with loss of precision of measurement. All instruments now use laminar sheath flow to minimize this problem (Crosland-Taylor, 1953). The suspension of cells is slowly injected into the center of a faster flowing stream of fluid; the latter provides a laminar sheath of fluid that surrounds, aligns and centers the cells (see Fig. 47-3B). In this way, channels with a diameter of 100 μm are in common use and cell flow is maintained in a very narrow central stream without clogging.

Light Scatter

There are two additional measurements freely available with every measurement of fluorescence using laser light excitation: forward or narrow angle light scatter, and right angle (wide angle) light scatter. Regardless of the fluorescence marker, the cell constituent measured, or the wavelength of excitation, it is possible to measure the intensity of the excitation laser light

deflected by the cell at narrow forward angles (2° - 5°) and at right angle (90°). **Forward angle scatter is an indicator of cell size** (Mullaney et al, 1969). **Right angle scatter is caused by intracytoplasmic organelles larger than $0.5\ \mu\text{m}$; thus, cells with more granular cytoplasm scatter more light at right angles.** These features were used by Salzman et al (1975) to distinguish different types of unfixed, unstained leukocytes in blood, and are now the basis for automated differential white blood cell counts of blood and bone marrow (Fig. 47-5).

Figure 47-5 Discrimination of unstained blood leukocytes by light scatter. Narrow angle (forward) scatter is on the vertical axis and wide angle scatter on the horizontal axis. The red blood cells are smaller than white cells and have lower forward scatter. The monocytes are slightly larger than other white cells and have slightly greater forward scatter, but the three classes of white cells (lymphocytes, monocytes, and granulocytes) differ primarily by wide angle scatter due to differences in cytoplasmic granularity. Basophils and eosinophils, which also have distinctive light scatter properties, are not shown here.

Pulse Width Measurements

Cell size can also be determined by "pulse width" measurements: by the duration of the fluorescence or light scatter pulse generated by the cell as it traverses a narrowly focused excitation beam (Sharpless et al, 1976). In a sense, this is the width of the shadow of the cell or the width of its fluorescence signal as it crosses and interrupts the excitation beam. Similarly, nuclear size can be determined by the width of a nuclear fluorescence pulse. These measures

of cell or nuclear size and cell granularity, as determined by forward angle or pulse width measurements and right angle light scatter, are useful in studies of all cell types.

Cell Sorting

Perhaps the single greatest limitation of flow cytometry is the inability to correlate visually classified individual cells with their particular measurements (see also **laser scanning cytometry**, below). Some clues come from studies of pure populations of cells, but only in strictly limited applications, such as the differential counts of peripheral blood cells. The correlations are usually not a problem in experimental studies of uniform cell populations, but they can be quite vexing

P.1714

in trying to analyze mixed cell populations in human clinical samples.

In an attempt to solve this problem, Ehrlich et al (1969) and Finkel et al (1970) scanned unstained cervical epithelial cells in flow using a **flying spot scanner**. Wheelless and Patten (1971, 1973) obtained low resolution information by analyzing the absorption or fluorescence pulse contours of cells traversing a thin band of excitation light (**slit scanning**). Kachel et al (1979) used a nanosecond flash that was activated by a cell volume sensor to capture cell images at a rate of 150/sec. None of these very imaginative approaches found further application.

Cell sorting by flow cytometry proved more successful. **It served two purposes: (1) diagnostic**, to select and inspect the cells with particular flow cytometry features or measurements so they can be classified visually, **(2) preparative**, in order to collect a pure population of cells chosen by flow cytometry for further biologic or biochemical study. Kamensky and Melamed (1967) devised a **diagnostic fluidic sorter** to determine if proposed spectrophotometric features had correctly identified cancer cells by flow cytometry of cervical cytology specimens. The selected cells were diverted into a side channel by a fluidic pulse and collected for later visual examination. While it served this purpose, sorting was slow and the sorted cells were frequently accompanied by other contaminating cells.

A faster and more efficient **preparative sorter** based on principles of the ink jet printer (Sweet, 1965) was adapted to an electronic cell sizing flow cytometer (Coulter counter) by Fulwyler (1965) and, several years later, to fluorescence measurements in a flow cytometer by Hulett et al (1969). The cells in the flow chamber are ejected downward through a narrow orifice where the stream in air intersects the excitation beam of laser light. There is an electrical charging collar at the orifice and, if a cell with previously defined characteristics is identified, the column of fluid receives an electrical charge. The stream is made to break into uniform droplets by an ultrasonic pulse. The droplets pass between charged electrostatic plates. If the droplet containing a cell is charged, it is diverted into a collecting vessel (Fig. 47-6). Sorting may have to go on for several hours to obtain the needed number of a small subset of cells, but the purity of the sample is very high. Chromosomes have been sorted in the same manner to obtain nearly pure populations of each chromosome for the human genome project (Gray et al, 1987). High-speed sorting has also been used to select pure populations of cytoplasmic organelles. Thus, the procedure is valuable for research, but technically demanding and time-consuming, and cannot be applied to routine examinations of clinical specimens.

FLOW CYTOMETRY COMPARED WITH HIGH-RESOLUTION IMAGE ANALYSIS

A comparison of these two methods is inevitable, though they are entirely different. Cell

analysis and classification by high resolution image analysis is based entirely on morphology (see Chap. 46), classification and analysis by flow cytometry is based primarily on the constituents and functional attributes of the cell, with less attention to morphology. The two methodologies are compared in Table 47-3.

Figure 47-6 Electrostatic droplet deflection cell sorter. The excitation laser beam is focused on the stream of fluid as it exits the orifice of the flow channel (observation point). When a desired cell is identified, a charging collar at the flow channel orifice gives a small, pulsed electrical charge that is retained as the cell stream breaks into droplets. The charged droplets containing the desired cells are deflected by a charged plate and are collected in a vessel. (From Shapiro HM. Practical Flow Cytometry, 3rd ed. New York, Wiley-Liss, 1995.)

PREPARATION OF BIOLOGIC SPECIMENS

Flow cytometry analyses can be performed on any cell suspension and have been carried out

on peripheral blood, bone marrow, effusions, spinal fluid, urine, sperm, bacteria, algae, plant cells and insect cells. These samples require little or no preparation because the component cells are already dissociated. It is also relatively easy to prepare single cell suspensions from cultured cells.

P.1715

TABLE 47-3 COMPARISON OF FLOW CYTOMETRY WITH HIGH-RESOLUTION IMAGE ANALYSIS

Measurements	Image Analysis	Flow Cytometry
Applicable to Cells	Fixed cells on slides	Fresh or fixed cells in suspension
Cell Selection	Selected by examiner	Non-biased selection of cells in the sample
Correlation With Light Microscopy	Yes	Difficult, needs preselection of cell type or cell sorting
Features Measured	Detailed cell and nuclear morphology. DNA content and nuclear texture	Global measurements of cellular and nuclear features, cytoplasmic texture. DNA, RNA, protein content, antigen expression. Proliferative status, apoptosis, other physiologic features, reactions over time. See Table 47-2.
Measurement Speed	Slow. Many measurements/cell	Very fast: 100-1,000 cells/sec Few measurements/cell
Stains and Probes	Absorbing	Fluorescent
Data Analysis	Complex	Rapid, often online
Data Presentation	Cell images and histograms	Histograms/graphics
Tissue Assays	Yes	No

On the other hand, solid tissues that are of interest to pathologists are not readily dispersed. The specimens easiest to process are samples obtained by fine-needle aspiration or by scraping the surface of a freshly resected surgical specimen. Paraffin-embedded archival

tissues are the most difficult to prepare and are limited to the study of nuclei. Regardless of the source of cells or nuclei, the preparation of cell or nuclear suspensions for flow cytometry requires strict attention to technical details, and is best performed by a skilled technologist.

Cell Dissociation From Fresh Tissues

A major limitation of flow cytometry is the **requirement for well preserved single cell suspensions**. Most human tumors are composed of a variety of coherent epithelial, stromal, and inflammatory cells. The cells of interest must constitute a large proportion of the specimen and, in clinical applications, not less than 15% to 20% of the total cell population (Hiddemann et al, 1984; Dressler and Bartow, 1989). Results vary depending on the tissue type and the type of measurements desired, i.e., whether they include cytoplasmic constituents, cell surface markers or simply intact nuclei. Squamous epithelial cells are tightly bound by desmosomes and are extremely difficult to isolate by any means. Even under the best of circumstances, the dissociation of solid tissues will inevitably yield small clusters of cells, broken cells, and cellular debris, but relatively few whole cells.

Two general methods are used: mechanical disaggregation or enzymatic digestion—or a combination of both. In the commonly used **mechanical method** of cell dissociation, the tissue in saline or tissue culture medium is minced into tiny fragments by cross-cutting with scalpel blades, and then separated into single cells by the shear forces produced by **syringing** through a small bore needle. Any residual fragments of tissue or stroma are removed by sieving through a nylon mesh. The downside of this procedure is that syringing causes progressive loss of cytoplasm and eventual total destruction of some cells. The degree of dispersion and cytologic preservation should be carefully monitored by visual microscopy (Wolley et al, 1976; Bijman et al, 1985; Ensley et al, 1987, 1993; Zalupski et al, 1993). Visscher and Crissman (1994) concluded that, in general, glandular tissues are equally well dissociated mechanically or enzymatically, but that enzymatic digestion is necessary to dissociate squamous epithelia. They recommend that fresh glandular tissue be placed in RPMI tissue culture medium in a Petri dish, bisected, and the cut surface gently scraped with a surgical blade to release the cells. The procedure can be repeated as necessary. The turbid suspension of cells is passed through an 80- μ m sieve, centrifuged, resuspended in RPMI, and fixed by adding 70% ethanol dropwise. Squamous tissues are treated before the sieving step with an enzymatic cocktail of trypsin, collagenase type II, DNase I.

Other methods include treatment of tissues with EDTA (ethylenediaminetetraacetic acid), pepsin, trypsin, collagenase and other proteases; no single method that is universally applicable (Wolley et al, 1979; Slocum et al, 1981; McDivitt et al, 1984; Costa et al, 1987; Smeets et al, 1987). Even without mechanical forces, the enzymatic disaggregation methods risk damage to cell surface molecules and may severely damage the cytoplasm. In general, the squamous cells, which have cytoskeletons rich in keratin, withstand disaggregation and retain cytoplasm better than the more fragile mucus-producing glandular cells. Finally, it should be noted that resistance to dissociation and to cell destruction varies among the cells within almost every tumor and every tissue, with resulting selection bias in the final cell sample.

P.1716

Nuclear Isolation Techniques

Fresh Solid Tissues

Isolated nuclei, free of nonspecific cytoplasmic fluorescence, provide optimum specimens for

DNA measurements by flow cytometry. Since cytoplasm is already partially or completely lost from many of the cells dissociated from solid tumors, particularly in needle aspirates, it becomes preferable to study whole nuclei that are completely stripped of cytoplasm.

The cell sample is obtained by aspirating with a fine bore needle (25 gauge) which is moved back and forth within the tumor, using little or no negative pressure, aspirating material into the bore of the needle, but not into the syringe. The same technique is used to sample tumors in vivo and in surgically resected specimens. The needle is flushed with 0.2 ml citrate buffer and the cell count checked in a hemocytometer. If there are fewer than 10^6 cells, repeat aspiration may be needed. The sample can be processed immediately or stored at -70°C in citrate buffer with dimethyl sulfoxide (DMSO). Of the methods proposed for nuclear isolation, that of Vindeløv and Christensen (1994A, 1994B) is generally preferred (see Appendix to this chapter). It is carried out on unfixed tissue, avoids potential selective cell loss during centrifugation steps, avoids clumping and staining artifacts due to fixation, and keeps cell numbers needed for the assay to a minimum. Vindeløv and Christensen recommend adding a mixture of chicken or trout nucleated erythrocytes as internal DNA control before staining the sample with propidium iodide. With recent advances in development of inexpensive, very stable solid state near-ultraviolet lasers, DAPI or (for live cells) Hoechst 33342 may be the preferred DNA fluorochromes. For description of these stains, see below.

Koss et al (1977) recommended the use of a citric acid-sodium citrate method for isolation of nuclei from epithelial tissues.

Archival Material

The obvious disadvantage of fresh tissue specimens is that they require prompt processing and often immediate examination in the laboratory. Several years may be required to collect and examine a reasonable series of any particular type of tumor to obtain data of clinical value. Thus, there was intense interest in reports by Hedley et al (1983, 1984, 1989) that intact nuclei could be extracted from archived tissue embedded in paraffin blocks and that it was possible to measure nuclear DNA in those specimens. This made it feasible to retrieve and examine a large series of accumulated cases with known clinical follow-up. A flurry of reports of such retrospective studies were published over the next several years. While variations in fixation, methods of preparation and staining, conditions of storage, etc. sometimes limited the precision of measurements, they were adequate to identify many tumors with abnormal DNA content. Specimen preparation technique is described in the appendix to this chapter.

Hematopoietic Specimens

Examinations may be carried out on whole or lysed blood or bone marrow, on specimens fixed in 1% buffered formaldehyde, or on fresh or paraffin-embedded lymph nodes, etc. Forward and side scatter measurements differ for lymphocytes, monocytes, granulocytes, platelets and red blood cells in fresh, unfixed specimens and these features can be used with **immunofluorescence** to select and classify mature and immature sub-populations by antigen expression. This is described and illustrated in a later section (see also Chap. 31).

STAINING METHODS

DNA Staining

DNA is one of the most commonly measured cellular constituents. It provides information on the proliferative status of a population of cells, as well as any gains or losses of DNA that often

accompany malignant transformation, as described in the following sections. Dyes that bind to and allow precise measurements of DNA are discussed briefly.

Propidium iodide is the most widely used DNA stain. It is an intercalating dye and requires RNase treatment of cells to remove double-stranded RNA. The dye was introduced by Crissman and Steinkamp (1973) as a DNA dye, in combination with fluorescein isothiocyanate (FITC) as a protein stain.

DAPI (4'-6-diamidino-2 phenylindole), which is arguably the most specific DNA dye (Kapuscinski, 1995), requires ultraviolet excitation, either with noncoherent light sources (mercury arc, xenon lamp) or a very expensive krypton laser, and is not widely used. However, there is now a relatively inexpensive solid state violet laser available which is capable of exciting DAPI and will, perhaps, be incorporated in moderately priced commercial cytometers.

Acridine orange (AO) is excited at 488 nm by the blue argon ion laser used in most commercial flow cytometers. It is a **metachromatic dye** that intercalates into double helical nucleic acids (DNA) to fluoresce green, and binds to single stranded nucleic acids (RNA) with red luminescence. The dye was studied extensively by Kapuscinski et al (1983, 1987) who elucidated the way in which it binds to single vs. double-stranded nucleic acids with a change in emission spectrum. Darzynkiewicz et al (1976, 1980) and Traganos et al (1977) made use of this property of acridine orange to develop a technique for simultaneous differential staining of DNA and RNA and, subsequently, to analyze chromatin structure as a function of denaturability of DNA (Darzynkiewicz et al, 1977, 1979). While it is a useful research tool, however, acridine orange requires carefully controlled staining conditions and has not gained wide clinical application.

Other DNA dyes less commonly used include: the vital stain **Hoechst 33342**, the antibiotics **mithramycin**, **chromomycin** and **olivomycin**, **ethidium bromide**, an analogue of propidium iodide, **TOTO-1** and **YOYO-1**, which

P.1717

are dimers of **thiazole orange**, and **7-amino actinomycin D**.

TABLE 47-4 SPECTRAL CHARACTERISTICS OF COMMONLY USED NUCLEIC ACID DYES

Dye	Excitation Maximum	Emission
Propidium iodide (PI)	536 nm	623 nm
Ethidium bromide (EB)	510 nm	595 nm
Acridine orange (AO)	480 nm (DNA)	520 nm (green)
	440-470 nm (RNA)	650 nm (red)
Hoechst 33342 (vital DNA stain)	340 nm	450 nm
DAPI	350 nm	470 nm

Chromomycin A ₃ (GC-rich DNA)	440 nm	555 nm
Mithramycin (GC-rich DNA)	440 nm	575 nm
7 Amino-actinomycin D ₃ (GC-rich DNA)	580 nm	660 nm
Hoechst 33258 (AT-rich DNA)	360 nm	460 nm

Excitation and emission spectra of these and several other more widely used DNA fluorochromes are listed in Table 47-4.

Stains for Immunofluorescence

The antibodies used for immune analysis of hematologic samples are labelled with **fluorescein isothiocyanate (FITC)** giving a green signal, **phycoerythrin (PE)** with an orange-red signal, and **peridinin chlorophyll protein (Per Cp)** giving a “far red” signal. A fourth red label, **allophycocyanin (APC)**, requires a laser of a different wavelength. These four labels can be used simultaneously on four different antibodies because contemporary flow cytometers switch lasers automatically. For a discussion of flow cytometric analysis of hematologic specimens, see below.

ANALYSIS OF DATA

Acquisition of Data

Any number of cells in a specimen may be examined by flow cytometry. The usual range is 5,000 to 20,000, but may be as many as 50,000 or even more. The number of cell features measured also varies. Usually, it includes the measurements of **light scatter**, narrow angle forward scatter (2°-5°), for cell size and right angle scatter for cytoplasmic granularity (see above). Depending on the staining procedure and capability of the instrument, from one to six or more different fluorescence signals per cell can be measured. Most instruments have a single laser and make two fluorescence and two scatter measurements. The measurements are collected in **list mode**, that is all the measurements on each cell are grouped together in a list of the cells measured. Thus, the cells can be classified by the relationship of measurements as well as absolute values, for example, the N/C ratio as well as absolute size of nucleus or cell.

Display of Data

Flow cytometric data may be displayed as histograms or scattergrams. Histograms are used to display a single set of values (for example, DNA content in a population of cells). Scattergrams allow either a comparison of two or more values in a single population of cells (for example, DNA and RNA content) or an analysis of multiple populations of cells, as used in hematopathology.

Histograms

Single measurements of interest can be displayed as a frequency histogram in which the arbitrary value of the cell (for example, its DNA content) is displayed on the abscissa and the number of cells in each category on the ordinates. The abscissa is arbitrarily subdivided into a

number of channels. For most practical measurements, the subdivision into 256 channels offers adequate accuracy, although a subdivision into 512 or 1024 channels is possible on many instruments. The height of the peak displayed on the ordinates represents the number of cells in each category (Fig. 47-7). For consistency of results and for comparison purposes, the histograms pertaining to a single entity (for example, a tumor type) should be adjusted to display a constant control value at the same channel number. The **calibration of the instruments** can occur with controls that may either be external (such as nucleated chicken or trout erythrocytes or fluorescent beads) or internal, recognized in the target histogram as a constant value (such as the diploid DNA content of normal lymphocytes). If desired, the developing histogram can be viewed on the monitor screen during measurements. Thresholds may be set to exclude small particles of debris, cell doublets, etc, or to decide when an adequate number of cells have been measured.

Scattergrams

Two measurements of interest in the same cell population can be displayed simultaneously as a two dimensional (bivariate) histogram or scattergram (Fig. 47-8) in which the

P.1718

two measurements of each cell are represented, respectively, on the abscissae and ordinates by the position of a single dot. This very common way of presenting data allows one to identify subpopulations of cells that have identical or similar measurements of two particular features and are, thus, represented by a distinct cluster of dots. It is particularly useful in comparing DNA content with some other measurement or in classifying leukemic cells by antigen expression (see later).

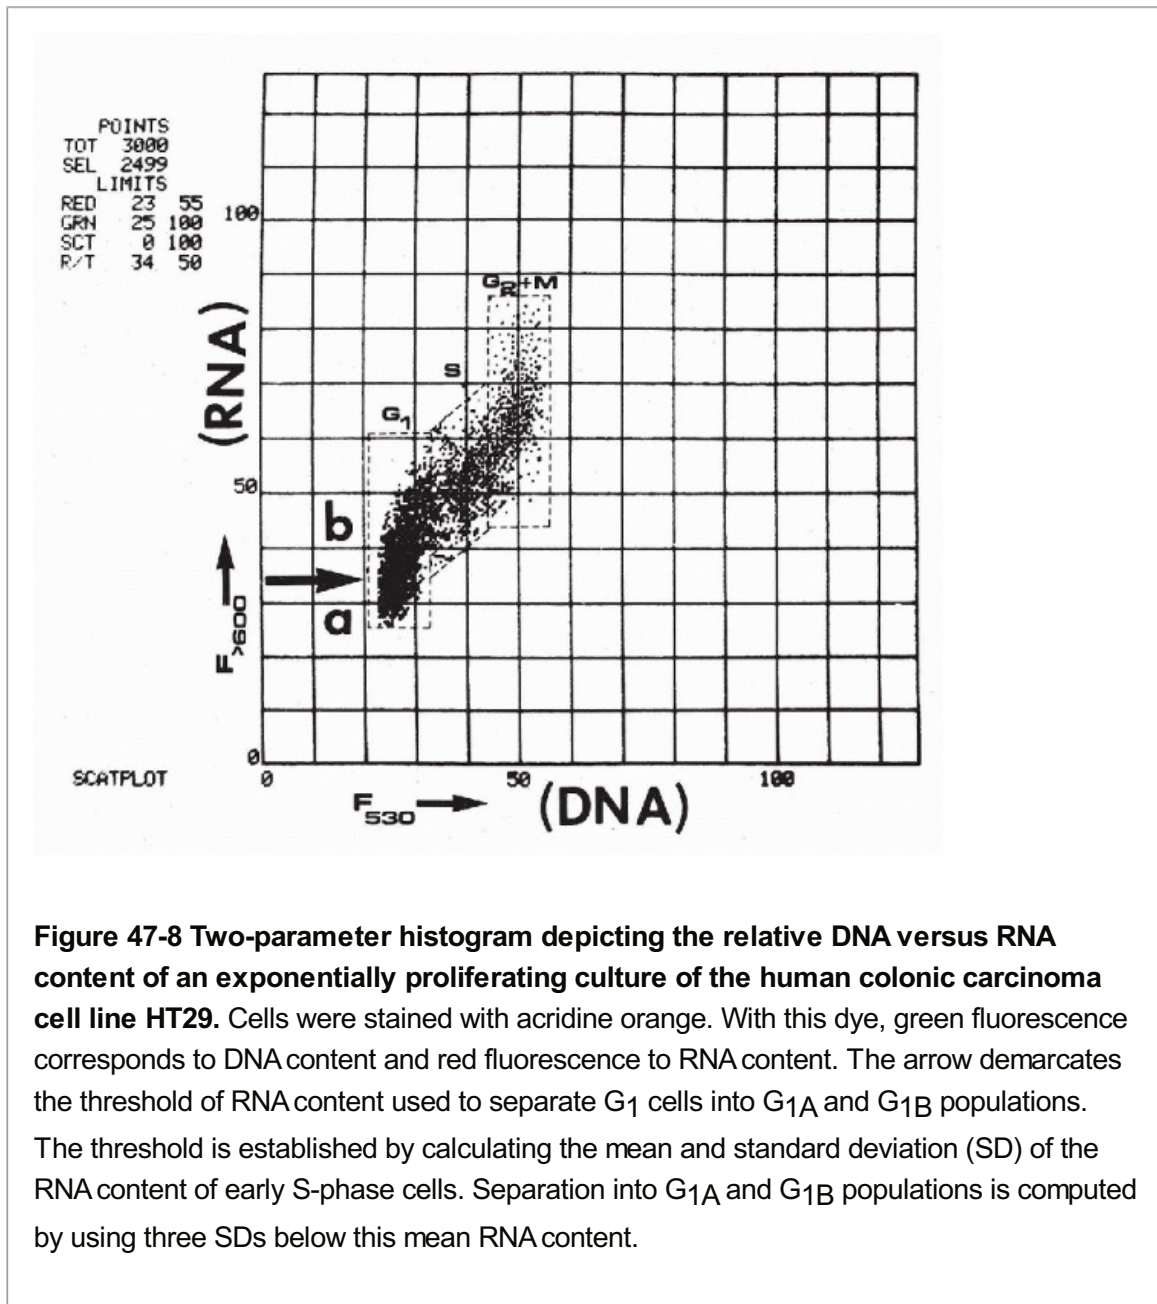

Figure 47-7 DNA histogram of proliferating HeLa cells in culture. *A* The intensity of red fluorescence of propidium stained cells is proportional to DNA content and is plotted on the abscissa in arbitrary units (channel numbers). The DNA diploid peak, containing G_0 and G_1 cells, is set arbitrarily at channel 50. Proliferating cells synthesize DNA during the S-phase and have increasing red fluorescence, reaching a maximum twice the diploid value (tetraploid) as they reach the G_2 M phase. The number of cells with the same or similar DNA content is indicated by the height of the histogram at each channel. *B* A computer-derived cell cycle distribution from the data in the histogram in (*A*) gives values of 60.73% for the (diploid) G_1 peak, 19.42% for S-phase cells, and 19.84% for cells in G_2 and mitosis. This histogram reflects the high proliferative index of this malignant cell line.

With a large number of dots in a cluster, the data can be presented as a pseudo-3-dimensional histogram in which the number of cells at each point is represented by the height of the peak (Fig. 47-9A,B). Other innovative techniques have been devised to display multidimensional data; for example, three-dimensional data may be displayed as a cloud of dots viewed

stereoscopically in a cubic space (Sharpless et al, 1979).

The use of scattergrams in the analysis of multiple cell populations in hematology is discussed below.

DNA Histograms

DNA measurements are the most common application of flow cytometry of solid tumors. The measurements of tumor, or suspected tumor cell populations, are customarily displayed as a single dimensional histogram. The interpretation of the DNA histogram follows the axiom that DNA content of normal, resting human cells is constant and is related to the number (46) and structure of the chromosomes, differing between individuals only with respect to the X and Y chromosomes (see Chap. 4).

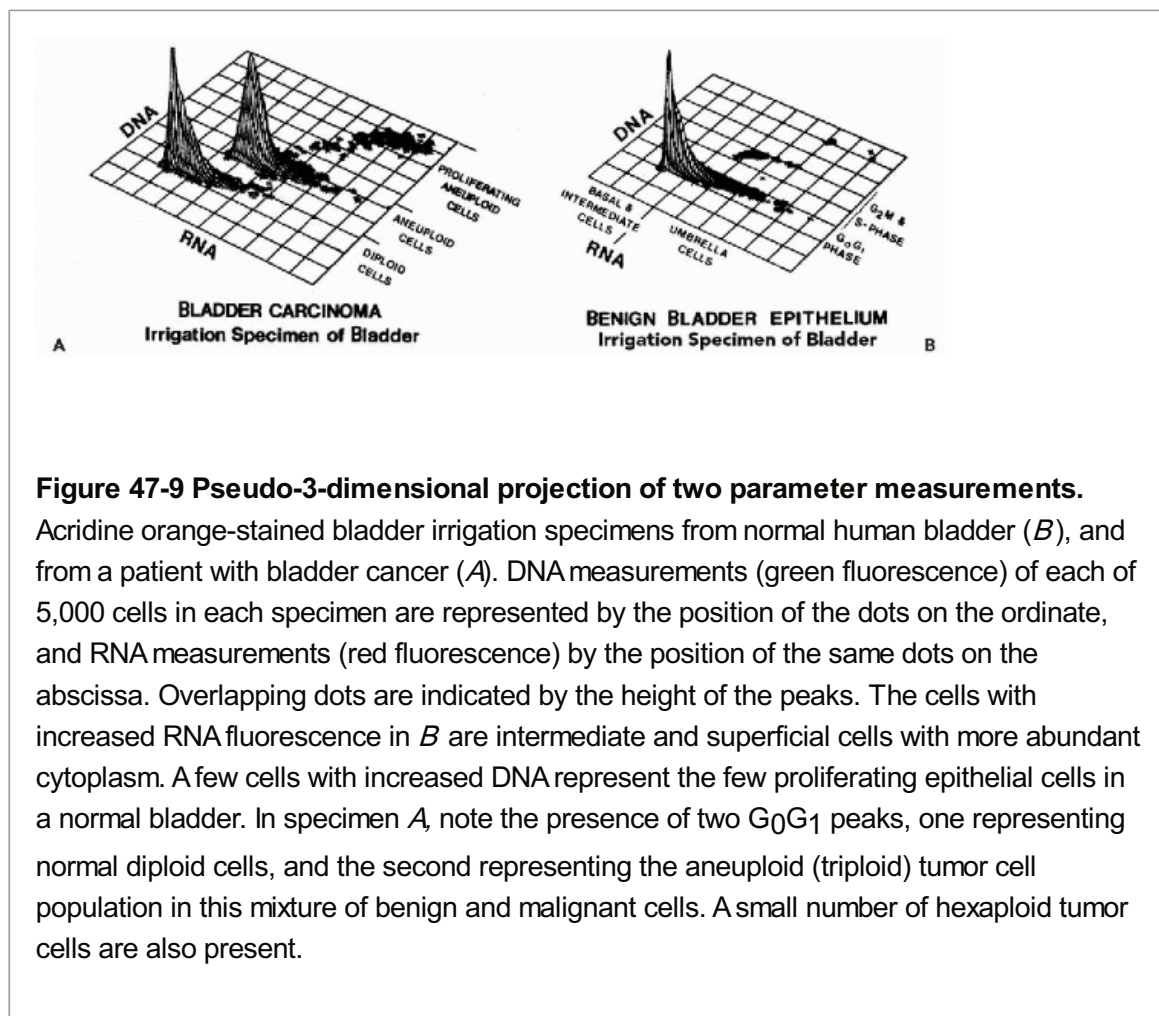

Most cells in benign populations are in resting phase (**G₀**) and are defined as having **diploid** or **euploid** DNA content. As these cells enter the cell cycle, but before the onset of DNA synthesis, they are defined as G₁ cells and are still diploid. Therefore, **G₀** and **G₁** cells are

grouped together and form the dominant left peak in the DNA histogram. The position of this peak in the histogram is usually set at an arbitrary constant value on the abscissa, commonly channel 50 in a 256 channel histogram.

As the G₁ cells begin to synthesize DNA, entering the **S-phase of the cell cycle**, there is a progressive increase in DNA content of the cells reaching double the resting value (G₂ phase), indicating the duplication of chromosomes (tetraploid cells). The tetraploid (**G₂ phase**) cells undergo mitosis and return to diploid DNA value. Because tetraploid cells and cells entering mitosis (prior to cell division) have the same DNA content, they form one peak known as **G₂M peak**. These events are reflected in the DNA histogram shown in Figure 47-7A. The fraction of cells in the normal G₂M peak should not be more than five percent. This is

P.1719

discussed further with respect to the proliferation of tumor cells.

The percentage of cells in each of the cell cycle compartments may be calculated manually or by computer (Fig. 47-7B). The Multicycle computer program, that is now available from Phoenix Flow Systems (San Diego, CA), provides semi-automated cell cycle analysis that minimizes subjective interpretation and further improves the precision and reproducibility of DNA histogram interpretation (Bergers et al, 1996). With improvements in instrumentation, in methods of specimen processing and measurement, and in standardization of instrumentation and data analysis, there continues to be increased consistency and reproducibility of results.

Changes in RNA content during the cell cycle can be correlated with DNA content in a 2-

dimensional scattergram (see Fig. 47-8). The interpretation of histograms in tumors is discussed in a later segment of this chapter.

Quality of DNA Histograms

With care in the preparation and staining of the cell sample, and with properly maintained high quality commercial instruments that are presently available, it is possible to achieve highly accurate and very precise DNA measurements by flow cytometry. Several mathematical calculations are commonly used to evaluate the quality of flow cytometry histograms. These include the coefficient of variation (CV), skewness, and kurtosis.

Coefficient of Variation

Precision of measurements is expressed as a CV. It is a measure of the tightness of the G₀G₁ peak, i.e., the variability of the DNA measurement. The CV is determined by dividing the mean channel number of the G₀G₁ population by its standard deviation, or sometimes approximated by measuring the width of the G₀G₁ peak at half height. The more uniform the measurements, the tighter the peak and the smaller the CV. While some investigators have reported CVs below 2%, which can be achieved with very uniform cells such as inactive lymphocytes, in general **CVs of 5% or less are considered adequate for clinical samples**. If the CV is greater than 7% or 8%, the peak may be composed of two or more populations that are not resolved. Often, it is irregular or asymmetric (skewed). Very large CVs, 10% or greater, are not acceptable and very likely represent deterioration of the specimen, poor specimen preparation or staining, or instrument failure.

Skewness

In histograms with CV of 3% or more, the shape of the G₀G₁ peak becomes important. If the peak is symmetrical, it almost certainly represents a single population. If it is very asymmetrical, that is highly skewed, there is a strong possibility of two overlapping cell populations. In that case, analysis of cell cycle distribution also becomes more complicated (see below).

Kurtosis

Kurtosis is a statistical function providing information on the shape of the peak, that is, whether it is sharp or flattened. Deviations from an integer value of 3 or more indicate a flat peak (decrease in peakedness). The value of kurtosis is calculated by an appropriate analytical computer program.

Controls

Standard controls have two functions: (1) to assure accuracy of the instrument and (2) to be sure that cell preparation

P.1720

and staining are optimal. Highly uniform **fluorescent microspheres**, that are available commercially, can serve as a reference marker to adjust instrument settings and maintain constant precision of DNA measurements. The microspheres of precise size and optical properties, including excitation and fluorescence emission spectra, are a useful reference for comparing the histograms and scattergrams of different populations of cells.

DNA reference standards are needed to evaluate DNA staining, ploidy and cell cycle distribution. **Peripheral blood lymphocytes** are often used for this purpose and may be

incorporated with the test sample (internal standard) or run separately (external standard).

Formalin-fixed, **nucleated chicken or trout red blood cells** can be used as either external or internal standards. They have the advantage of being a hypodiploid marker (33% and 80% of human diploid cells, respectively) and, therefore, do not overlap with the DNA distribution of human cells.

DNA ANALYSIS OF TUMORS

Tumors can be either diploid or aneuploid. Tumors with **diploid or near-diploid DNA content** display histograms identical, or similar, to those of normal cells in cell cycle. Diploid DNA content by flow cytometry does not necessarily signify normal chromosomal karyotype. The measurements of total cellular DNA are not sensitive to translocations or inversions, in which there is no change in total DNA content, or to combinations of gene amplification or loss accounting for less than 2% change in total DNA.

Tumors with abnormal chromosomal content and measurably abnormal DNA content are defined as **aneuploid**. In such tumors, the histogram distribution of DNA measurements is shifted, almost always to higher values. In a mixture of malignant and benign cells, which is usually the case in human tumor specimens, there is superimposition of benign and malignant DNA distributions. The striking result is the presence of two (or more) G₀G₁ peaks (Fig. 47-9A), which may be compared with the single peak seen in a corresponding benign epithelial specimen (Fig. 47-9B). The abnormal second population is, by definition, aneuploid. If the G₀G₁ peak of the aneuploid tumor cell population is located to the right of the benign population on the abscissa of the histogram, the tumor is said to be **hyperdiploid**; if located to the left of the G₀G₁ peak, it is **hypodiploid**, as is the case in some leukemias and, exceptionally, in solid tumors. Hyperdiploid tumors may be **triploid** (G₀G₁ peak of the tumor cells lies midway between the G₀G₁ and G₂M peaks of the benign population), **tetraploid** (G₀G₁ peak of the tumor cells overlies, and is higher than, the G₂M peak of the benign population), or **hypo- or hypertetraploid** (Fig. 47-10).

The ratio of the position of the G₀G₁ peak of the tumor cells to that of the benign cell population, on the abscissa of the histogram, is known as the **DNA index (DI)** (Hiddemann et

al, 1984). Thus, for diploid tumor cells where both peaks occupy the same position, the DI is 1.0. For tetraploid cells, the DI is 2.0. DI of 1.5 indicates a triploid population. As is the case with histograms of normal cycling cells, the percentage of tumor cells in each of the G₁, S and G₂M phases of the cell cycle can be determined from the histogram, providing information on **cell cycle distribution** and an indirect **measure of proliferation** (see below and Fig. 47-7).

While there is inevitably some variation in measurements of a given test specimen among laboratories or, indeed, from different samples of the same tumor in a single laboratory, a reasonably good interlaboratory reproducibility for DNA index of tumors has been reported based simply on inspection of DNA histograms (Coon et al, 1988; Wheelless et al, 1991).

Cell Proliferation in Tumors

One of the common applications of flow cytometry is in analysis of events in the cell cycle (see Fig. 47-7). Much of our present understanding of the molecular controls of proliferation and differentiation in normal and neoplastic cells comes from studies using flow cytometry (for review, see Darzynkiewicz et al, 2001). The complexity of the molecular events governing the G₁-S transition is illustrated in Figure 47-11.

It is almost axiomatic that rapidly growing tumors are more aggressive and have a less good prognosis than slowly growing tumors. This can be demonstrated clinically by actually measuring tumor growth over time or cytologic preparations, by counts of cells in mitosis, or by immunostaining with antibodies to proliferation antigens such as Mib1 (see below and Chap. 45).

P.1721

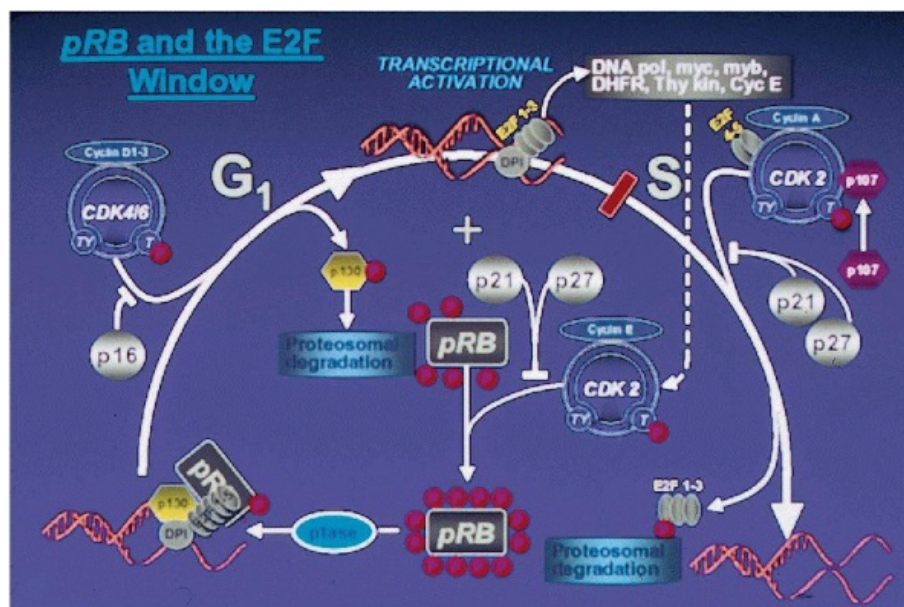

Figure 47-11 Diagrammatic representation of the G₁-S phase transition of the cell cycle, demonstrating the key role of the retinoblastoma gene product (pRb) and some of the many molecular controls. Much of our understanding of these processes comes directly from flow cytometry studies. (Courtesy of Dr. Frank Traganos, New York Medical College, Valhalla, NY.)

In single parameter flow cytometry histograms of DNA content, it is customary to represent the percentage of proliferating cells by either of one or two indices: proliferative fraction (PF) [equivalent to proliferation index (PI)] or S-phase fraction (SPF). **The proliferative fraction, PF (or proliferation index PI)** is defined as the percent cells with greater than diploid DNA in the histogram. The **S-phase fraction (SPF)** is defined as the percentage of cells with greater than diploid, but less than tetraploid, DNA (see Fig. 47-7). These indices are determined from the DNA histogram and are the simplest measures of proliferation.

The two fractions may be determined by setting appropriate thresholds based on the shape of the histogram. Alternatively, there are interactive computer programs that use mathematical models of cell cycle distribution to analyze the histogram and calculate the percent cells in each of G₀ G₁, S, and G₂M phases of the cell cycle (see Fig. 47-7B). They vary from simple graphic programs, that mimic the human approach, to highly complex mathematical methods, that use curve-fitting algorithms (Fried, 1976; Dean, 1990; Gray et al, 1990; Rabinovitch, 1994) and correct for cellular debris (Bagwell et al, 1991).

Unfortunately, most solid tumors are heterogenous and it may not be possible to sharply demarcate the G₀G₁ from S and S from G₂M phases of the cell cycle, even with sophisticated computer programs. Also, cell suspensions often contain aggregates, as well as single cells, in mixed populations of differentiating and dying epithelial and reactive stromal cells and leukocytes. Finally, aneuploid tumors may have overlapping cell cycle distributions with multiple peaks and it may not be possible to determine the percent proliferating cells. Thus, PF and SPF values typically have wide measurement variance.

Determination of DNA Synthesis by Bromodeoxyuridine Labeling

For many years, one of the most widely used experimental techniques for identifying and quantifying proliferating cells was by labeling newly forming DNA in the replicating cells with **radioactive (tritiated) thymidine**. Tritiated thymidine was introduced into cell or tissue cultures in vitro, or given intravenously in vivo to experimental animals, and was incorporated into replicating DNA of proliferating cells during S-phase of the cell cycle. Thymidine-labeled cells were subsequently identified in autoradiographs. The procedure was lengthy and tedious and required care in working with radioactive material.

A nonradioactive analogue of thymidine, **bromodeoxyuridine (BrdUrd)**, which was substituted for thymidine by Gratzner et al (1975, 1982) and his colleagues (Dolbeare et al, 1983), greatly simplified and shortened the process, and made it amenable to measurements by flow cytometry. A fluoresceinated antibody was used to label the cells that incorporated BrdUrd. All cells were counterstained with a

P.1722

fluorescent DNA dye of another color. Counts of labeled versus total cells were carried out by dual parameter flow cytometry. **This method yields the most precise measurements of percent S-phase cells** (Fig. 47-12A,B). Freshly resected human tumors can be labeled in vitro, but penetration of BrdUrd into the tissue is poor. Also, some cells die rapidly after the tumor is resected. Thus, for solid tumors, the results are much more accurate if BrdUrd is given intravenously in vivo prior to surgery with patient consent. The drug has been given without ill effects in much higher doses as a radiation enhancer for patients undergoing radiotherapy and it has virtually no side effects in the dose used for labeling S-phase tumor cells.

Proliferation Associated Antigens: Cyclins and Cyclin-Dependent Kinases and

Inhibitors

The last few years have seen advances in our understanding of the complex machinery controlling cell proliferation, much of it from ingenuous flow cytometry studies employing newly developed antibodies to proliferation associated antigens of the cell. Among the first and still most widely used are Ki-67 (or Mib1) (Gerdes et al, 1984; Baisch and Gerdes, 1987) and proliferating cell nuclear antigen (PCNA/Cyclin) (Celis et al, 1984). Little is known about the antigen of Ki-67, but PCNA is known to be a component of DNA polymerase δ (Bravo et al, 1987).

At this writing, we recognize **three key families of components controlling the cell cycle: (1) cyclins, (2) cyclin-dependent kinases (CDKs), and (3) CDK inhibitors (CKI)**. There are at least eight different cyclins (A-H), each of which is transiently expressed at different phases or “checkpoints” in the cell cycle of benign proliferating cells.

The CDKs are activated by binding to a corresponding cyclin. The resulting complex phosphorylates a specific set of proteins that acts at a particular successive checkpoint or phase of the cell cycle. Of the several CDKs, the **most important is CDK4/6 which complexes with cyclin D to phosphorylate the retinoblastoma gene protein (pRb) and initiate cell entrance from G₁ into S-phase**. CDK2 complexes with cyclin A during transition from late S-phase to G₂. It also complexes with cyclin E and phosphorylates histone H1 at the G₁ to S-phase transition. CDK1 is complexed with cyclin B₁ during the G₂ to M transition (see Fig. 47-11).

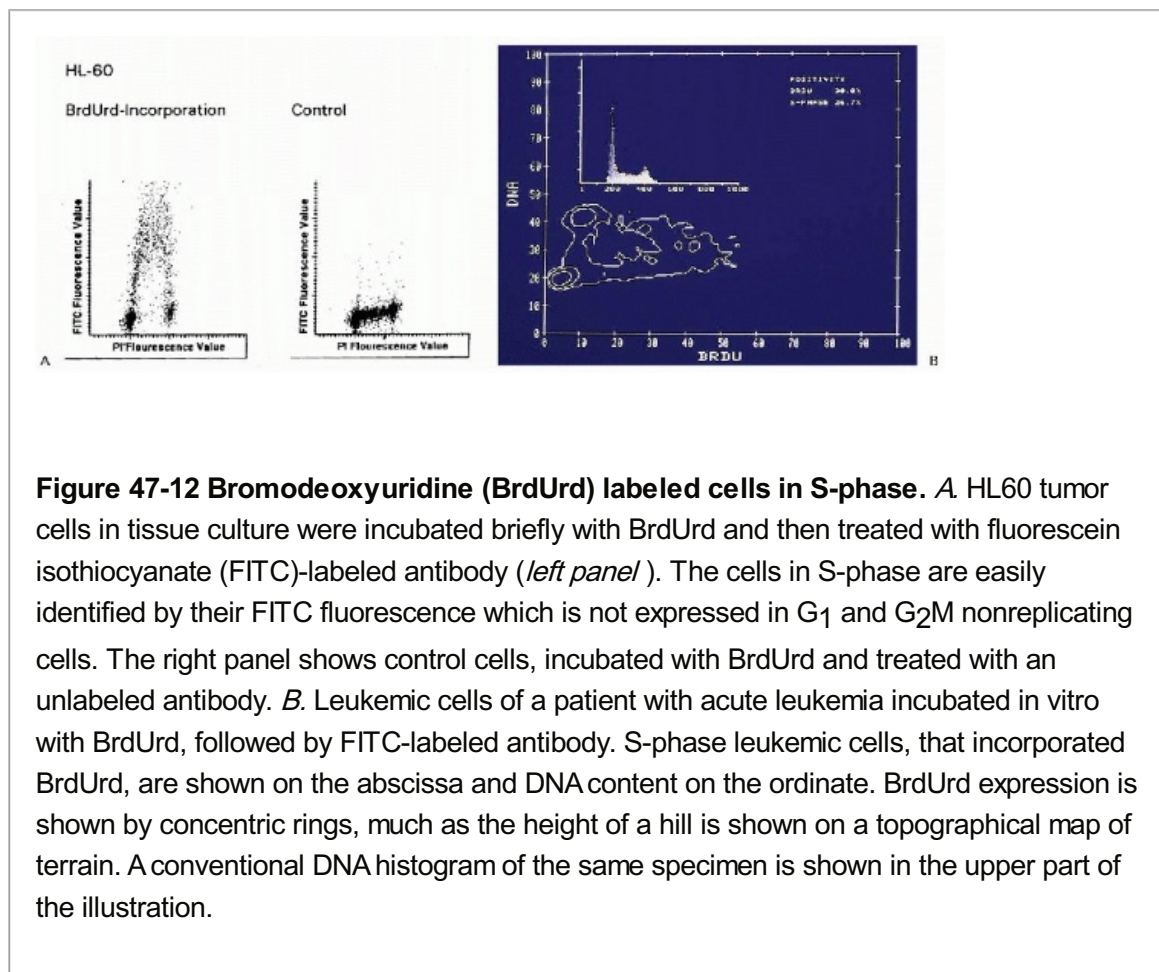

Figure 47-12 Bromodeoxyuridine (BrdUrd) labeled cells in S-phase. A HL60 tumor cells in tissue culture were incubated briefly with BrdUrd and then treated with fluorescein isothiocyanate (FITC)-labeled antibody (*left panel*). The cells in S-phase are easily identified by their FITC fluorescence which is not expressed in G₁ and G₂M nonreplicating cells. The right panel shows control cells, incubated with BrdUrd and treated with an unlabeled antibody. B. Leukemic cells of a patient with acute leukemia incubated in vitro with BrdUrd, followed by FITC-labeled antibody. S-phase leukemic cells, that incorporated BrdUrd, are shown on the abscissa and DNA content on the ordinate. BrdUrd expression is shown by concentric rings, much as the height of a hill is shown on a topographical map of terrain. A conventional DNA histogram of the same specimen is shown in the upper part of the illustration.

The two most important tumor suppressor genes are p53 and pRb as discussed in Chapter 7.

The protein product of the gene p53 induces the CDK inhibitor p21 and blocks cell entrance into S-phase of cells with faulty DNA. Similarly, the CDK inhibitors p15 and p16 prevent activation of cyclin D1-CDK4 and block pRb phosphorylation. Cells with uncorrected DNA defects are prevented from entering the cell cycle by the action of these two tumor suppressor genes. But overexpression or mutation of cyclins and/or CDKs can disable p53 or pRb and transform them into activated oncogenes, permitting cells with mutated DNA to enter the cell cycle and replicate.

The cyclins can be studied at the individual cell level by multiparameter flow and by laser scanning cytometry. As an example, Gorczyca et al (1997) were able to show that cyclin B₁, which is normally expressed transiently at the S-G₂M boundary, is no longer restricted to a particular phase of the cell cycle in malignant tumor cells and, in its defective form, may account for unrestrained cell proliferation.

There are many other components of the machinery controlling cell proliferation that may be mutant or disordered in malignant tumor cells (Cordon-Cardo, 1995) and can be studied at the level of the individual cell by flow cytometry. These include, not only the other cyclins and cyclin

P.1723

dependent kinase inhibitors (e.g., p21, p16, p27), but also defective interactions with key proteins, like the retinoblastoma gene protein product (pRb) (Bartek et al, 1997) and its phosphorylation status (Juan et al, 1998).

As a result of these developments, it may soon be possible to identify the specific defect(s) responsible for unrestrained cell growth in a given tumor and then to correct or block its effect. Currently, that is the goal of much cancer chemotherapy research. A first dramatic example was in the treatment of chronic myelogenous leukemia associated with the bcr-abl tyrosine kinase gene product of the Philadelphia chromosome described in Chapter 4. Gleevec (Novartis Pharmaceuticals Corporation, East Hanover, NJ) is a selective inhibitor of this kinase, designed with knowledge of its molecular structure and function. The drug has produced a remarkable hematologic response in 95% of 454 patients who had failed prior conventional therapy (Kantarjian et al, 2002).

FLOW CYTOMETRY OF APOPTOSIS

The normal balance of cell proliferation and cell loss is disturbed in tumors. As discussed in Chapter 6, **there are two forms of cell death: necrosis**, a passive process in which death is due to effects of an external agent such as ischemia, loss of nutrition or toxic, thermal or physical damage, and **apoptosis** (Greek, *apo* = "from" or "off," *ptosis* = "to fall"), which is the most important mechanism of tumor cell death. It is also known as **programmed cell death** and may be controlled genetically during development as, for example, in loss of the tadpole tail during maturation into a frog. In tumors, the relative proportion of cells in apoptosis does not keep pace with proliferation and may prove as important a prognostic indicator as the proliferative or mitotic index.

The gold standard for identification of apoptosis is still based on cell morphology. As described in Chapter 6, the change in cell morphology is due to nuclear fragmentation within an intact nuclear membrane (karyorrhexis). The DNA strand breaks (DNA ladder), that define apoptosis, account for the nuclear fragmentation and can be labeled with biotinylated deoxyuridine triphosphate (dUTP) (end labeling), catalyzed by exogenous terminal deoxynucleotide transferase (TdT) or by DNA polymerase (nick translation). A number of flow cytometry techniques for identification of apoptotic cells may be used (for review and critique, see

Darzynkiewicz et al, 2001). These include methods based on identifying DNA strand breaks, loss of mitochondrial transmembrane potential (Rhodamine 123 staining), caspase activation and cell surface exposure of phosphatidylserine (annexin V binding). The apoptotic cells, visualized with a fluorochromed avidin-conjugated antibody, can be quantified by flow or laser scanning cytometry (Fig. 47-13). A somewhat simpler, more direct method of demonstration of apoptosis was introduced later by Li et al (1995, 1996) using directly fluoresceinated deoxynucleotides to label the DNA strand breaks in apoptotic cells. The latter procedure, also known as **Tunnel reaction**, is also applicable to histologic material.

Figure 47-13 Apoptotic cells. The breaks in the DNA “ladder” in cells undergoing apoptosis are labeled with biotinylated dUTP (deoxyuridine triphosphate) using the enzyme TdT (terminal deoxynucleotide transferase) and detected by fluoresceinated avidin (Gorczyca et al, 1993). The labeled ends of DNA breaks are shown here as punctate green fluorescence, intact DNA is counterstained with propidium iodide and fluorescent red. Two-parameter flow cytometry, or laser scanning cytometry, can be used to determine the ratio of apoptotic to normal cells. (Courtesy of Dr. Z. Darzynkiewicz, New York Medical College, Valhalla, NY.)

Many of the hormonal and anticancer chemotherapeutic drugs act by inducing apoptosis. The percentage of apoptotic tumor cells in leukemic patients was studied by Gorczyca et al (1993) as a possible measure of therapeutic effect and, in patients with the myelodysplastic syndrome, by Raza et al (1995) as a potential prognostic indicator. There are now reports of human leukemias that have been studied in vivo during therapy to determine drug induction of apoptosis (Deptala et al, 1999). Spontaneous and drug-induced apoptotic cell death in human solid tumors was studied by flow cytometry of fine needle aspirates, in which the percentage of apoptotic cells varied greatly, but was higher among aneuploid than diploid tumors and was unrelated to the S-phase fraction (Gorczyca, 1994).

ENRICHMENT OF SELECTED CELLS

The complex population of cells obtained from most solid tumors includes leukocytes, stromal

and endothelial cells that dilute and sometimes obscure a small population of aneuploid tumor cells. Thus, it is important to select tissues that contain as large a proportion of viable tumor cells as possible. If necessary, the tumor cells may be concentrated by techniques that include mechanical sieving and **differential sedimentation** (Tolles, 1979; Walle et al, 1983). Certain populations of lymphoid or epithelial cells can be sorted and separated from inflammatory and stromal cells by taking advantage of **uniquely expressed cellular antigens**. In the latter approach, magnetized microspheres (<100 nm diameter) are coated with antibodies specific for surface antigens expressed by the cells to be sorted. The cell sample is mixed with the antibody-coated microspheres, which are bound by cells expressing the specific antigen. The cells with bound microspheres are separated from remaining cells in a high gradient magnetic field (Miltényi et al, 1990). Cell viability is not affected. These bulk separation techniques

P.1724

have an advantage over cell sorting by flow cytometry in that large populations of cells can be processed in a few minutes, making it preferable for concentrating rare cells.

Epithelial tumor cells have been selected from mixed populations of cells for DNA measurements by thresholding on **cells expressing cytokeratin antigens** in dual parameter flow cytometry. While, in principle, dual parameter flow cytometry is very attractive, in practice there is biased selection of tumor cells that survive the traumatic process of specimen collection and cell preparation (lymphomas are an exception, see below). Many epithelial tumor cells lose their cytoplasm and no longer express cytokeratin antigens.

DNA FLOW CYTOMETRY OF SOLID TUMORS

With the progressive development and widening clinical application of cytogenetic and quantitative cytometry techniques, it became evident that **many, though not all, human solid malignant tumors were composed of cells with abnormal DNA content**, corresponding to chromosomal abnormalities (reviewed in Barlogie et al, 1980, see also Chaps. 4 and 7). Many studies were undertaken in the succeeding decades to determine whether the degree of abnormality, as reflected in abnormal DNA ploidy levels, or in the proliferative activity of the tumor (as expressed by the S-phase fraction), were of prognostic value. For selected, often well differentiated tumors, it was concluded that a diploid, or near diploid, DNA modal pattern had a more favorable clinical course. In poorly differentiated aneuploid tumors, it was difficult to prove that DNA content had independent prognostic significance. The S-phase fraction reflecting proliferation was generally given more weight than DNA ploidy but was usually greater in aneuploid tumors, perhaps in part because S-phase of aneuploid tumors was overestimated in complex histograms.

Finally, there were many inconsistencies in the results of these studies, best attributed to technical differences in the way they were carried out. Among these are: studies of archived, paraffin-embedded tissue versus fresh tissue, sampling errors, particularly in comparing studies of single samples with multiple samples of a specimen, mechanical vs. enzymatic dissociation of cells, differences in staining technique, and, not least, differences in histogram quality and the definition of aneuploidy. Despite all of this, there remains a general consensus about the prognostic value of DNA cytometry for the various common human tumors. This is summarized in Table 47-5, reflecting the opinion of the writer. For detailed reported results, the reader is referred to the bibliography at the end of this chapter and to an exhaustive review by Cornelisse and Tanke (1997).

Human Cancers With Strong Correlation of DNA Histogram and Prognosis

Carcinoma of Urinary Bladder

While voided urine provides desquamated urothelial cells in suspension, they are often degenerated and seldom present in abundance. Hence, bladder irrigation or barbotage specimens are preferred for flow cytometry (Badalament, 1987; Wijkstrom et al, 1987; Hermansen, 1990). They provide suspensions of desquamated urothelial cells that are present in abundance, well preserved and ideal for cytometric study. The DNA content of tumors of the urinary bladder have been extensively studied by Tribukait et al in Sweden (Tribukait et al, 1978, 1979, 1982; Gustafson et al, 1982), by Vindeløv et al in Denmark (1995), by Collste et al (1979, 1980) and Melamed et al (1984, 1990, 1992) in the United States. In retrospective and prospective studies, it was shown that there is excellent correlation between DNA ploidy, histologic classification, and clinical behavior. Grade 1 noninvasive papillary tumors (papillary tumors of low malignant potential) are typically diploid and unlikely to progress to invasive carcinoma. In fact, the presence of an aneuploid population in a specimen from a patient with a low grade papillary tumor strongly suggests that a co-existing high grade tumor is also present and may have been overlooked. High-grade papillary tumors and invasive carcinomas are virtually always aneuploid, as are the flat carcinomas in situ from which most invasive carcinomas are derived (see Fig. 47-9A). Intermediate grade tumors may be diploid or they may have an aneuploid or tetraploid population and usually also increased S-phase fraction. Vindeløv et al (1995)

P.1725

found S-phase fraction to be an independent predictor of survival for patients treated by irradiation. Tetraploid tumors generally have a better prognosis than nontetraploid aneuploid tumors. Koss et al (1989) compared DNA measurements by flow cytometry and image analysis in bladder washings of 50 patients with urothelial tumors. In 14 patients with either diploid or questionable flow cytometric histograms, aneuploidy could be documented by image analysis. Regardless of the technique used, aneuploid DNA pattern was indicative of recurrent high-grade tumors, including several carcinomas in situ.

TABLE 47-5 DNA PLOIDY AND S-PHASE FRACTION AS PROGNOSTIC FACTORS IN SELECTED GROUPS OF HUMAN TUMORS	
Strong

Lung carcinoma

Uterine cervical carcinoma

Head and neck squamous carcinoma (excluding oral)

Renal carcinoma

Wilms' tumor

Neuroblastoma

None

Thyroid tumors

Other endocrine tumors

Gastric carcinoma

Klein et al (1982) found 88% of 43 patients with papillary carcinoma in situ and 98% of patients with flat carcinoma in situ to have diagnostic evidence of carcinoma by flow cytometry of bladder washings. The presence of an aneuploid population has proved at least as sensitive an indication of bladder cancer as a series of three conventional voided urine cytology specimens (Badalament, 1987).

Brief mention should be made of RNA measurements of bladder tumors. Klein et al (1982), using the acridine orange staining technique of Darzynkiewicz (1976, 1994) and Traganos (1977), found that 80% of low-grade papillary tumors, most without abnormal DNA distribution, had increased cellular RNA. He concluded that dual parameter DNA/RNA flow cytometry was more sensitive to low-grade tumors than DNA measurements alone.

Flow cytometry of barbotage specimens has also been effective in evaluating the results of conservative surgery and in following patients who know they are at risk of recurrence and will accept this minimally invasive procedure (Devonec et al, 1982; Klein et al, 1982). It has been effective, as well, in monitoring intravesical BCG treatment of low stage bladder carcinoma (Staiano-Coico et al, 1985; Badalament et al, 1986; Bretton et al, 1989) and flat carcinoma in situ (Klein et al, 1982), and monitoring the efficacy of chemotherapy (Hermansen et al, 1988). However, flow cytometry is not proposed as a detection or diagnostic technique for patients who would not otherwise be subject to catheterization or cystoscopy.

In a consensus statement, after reviewing the role of flow cytometry in the diagnosis and management of tumors of the urinary bladder, members of an NCI review committee recommended flow cytometry for evaluation of patients suspected of bladder tumor, or at risk of recurrence after successful conservative treatment, such as transurethral resection, intravesical BCG, or irradiation (Aamodt et al, 1992; Wheelless et al, 1993). Flow cytometry was not considered practical for screening asymptomatic populations not known to be at high risk of bladder cancer. For further comments of DNA ploidy in tumors of the bladder, see Chapter 23.

Prostatic Carcinoma

In most prospective and retrospective studies, DNA diploid prostatic carcinomas have a significantly better prognosis than aneuploid tumors (Zetterberg and Esposti, 1980; Lundberg et al, 1987; McIntire et al, 1988; Winkler et al, 1988; Adolfsson et al, 1990; Tribukait et al, 1991). The ploidy patterns correlate well with tumor grade and stage, most localized tumors in stage A are diploid, whereas most of the advanced carcinomas in stages C and D are aneuploid or tetraploid. A single-needle aspirate or small needle biopsy is subject to sampling error. For example, lack of correlation of aneuploidy with high cytologic grade, reported by Ritchie et al (1988), suggests that a sampling error occurred. In studies of pelvic lymph node metastases of prostatic carcinoma, in which sampling error could be excluded, Stephenson et al (1987) documented that metastatic diploid cancers were less aggressive than aneuploid. A consensus conference of the World Health Organization (WHO) on early diagnosis and prognosis of localized prostatic carcinoma concluded that aneuploid tumors can be expected to respond very poorly to either irradiation or endocrine treatment, and that aneuploidy was an ominous prognostic sign (Schröder et al, 1994).

As noted, DNA ploidy correlates with histologic grade, at least for Gleason high-grade versus low-grade tumors but, for the majority of carcinomas that are of intermediate grade, the prognosis is unreliable. It is tempting to suggest that the large number of occult prostatic cancers, observed incidentally in elderly men at autopsy, may be predominantly diploid, indolent tumors with low S-phase fraction. Evidence to support this can be found in the work of Lundberg et al (1987) who used a combination of ploidy values with histologic grading to predict which patients would die of their tumors and which would die of other causes. In a retrospective study at about the same time, Fordham et al (1986) reported that only 15% of diploid tumors had progressed locally or metastasized, whereas 75% of tumors with an abnormal DNA distribution pattern progressed during follow-up periods of 5 to 19 years. None

of their patients with diploid tumors died of prostatic carcinoma. Adolfsson et al (1990) followed 72 patients with untreated prostate cancer by repeat FNA aspiration biopsies for a minimum of 2 years. Nearly one-fourth of the patients had increasing aneuploidy and cytologic dedifferentiation during this time. These studies carry important implications for the patients with localized, low- or intermediate grade carcinoma who may consider watchful waiting as an alternative to a major therapeutic intervention (e.g., prostatectomy) with its potentially major complications, such as impotence and incontinence. For further comments on this topic, see Chapter 33.

Barrett's Esophagus and Esophageal Carcinoma

In patients with Barrett's esophagus **5% to 20%** may develop adenocarcinoma, a disease that has been increasing dramatically over the last two decades. The patients with significant atypia (i.e., "dysplasia") of the metaplastic gastric mucosa are at highest risk of carcinoma (see Chap. 24). At the University of Washington in Seattle, the 5-year cumulative cancer incidence in patients with high-grade dysplasia is 59% (Reid et al, 2000). In patients with negative, indefinite or low grade dysplasia, the probability of carcinoma is closely related to DNA ploidy. For DNA diploid lesions, it is 0% at 5 years; for nondiploid lesions, it is 28% (Reid et al, 2000). A DNA histogram with tetraploid population in excess of 6% or aneuploid DNA population greater than 2.7N was highly predictive of cancer (Rabinovitch, 2001). At Westchester Medical Center (Valhalla,

P.1726

NY), patients with dysplasia, whether high or low grade, are presently considered for local ablative procedures by endoscopic laser cautery. It may be possible to limit the treatment to those who have low-grade lesions with diploid DNA. Also, because endoscopic surveillance and biopsies that are required to identify dysplastic glandular mucosa are subject to differences in interpretation, flow cytometry has the potential to be a reliable, objective marker for risk of carcinoma. For example, one of three biopsies of Barrett's esophagus from a 72-year-old man, illustrated in Figure 47-14A, was variously interpreted as indefinite for dysplasia vs. low-grade dysplasia but proved to be aneuploid (Fig. 47-14A, inset), indicating increased risk of carcinoma. Biopsies from other sites at the same time showed similar atypia but a normal DNA distribution (Fig. 47-14B and inset). Thus, **flow cytometry studies of Barrett's esophagus promise to be one of the most practical applications of flow cytometry of human solid tumors.**

Haraguchi et al (1995) studied DNA ploidy in 56 patients with in situ and superficially invasive squamous carcinomas of esophagus and found DNA aneuploidy in 40, with heterogeneity of ploidy and increased probability of recurrence in the larger tumors following resection.

In a study of tumor cell proliferation, Haustermans et al (1994) examined 27 squamous and 32 distal adenocarcinomas of esophagus following preoperative intravenous iododeoxyuridine (IUDR is comparable to BrdUrd for labeling S-phase cells, see above) and found a mean potential doubling time of about 4.5 days for squamous and 5.5 days for adenocarcinoma. Most carcinomas were rapidly proliferating, though there was considerable intra-tumor variability between biopsies from different sites of the same tumor. The overall prognosis for invasive esophageal carcinoma is dismal and it is unlikely that small differences in proliferation will affect prognosis (see also Chap. 24).

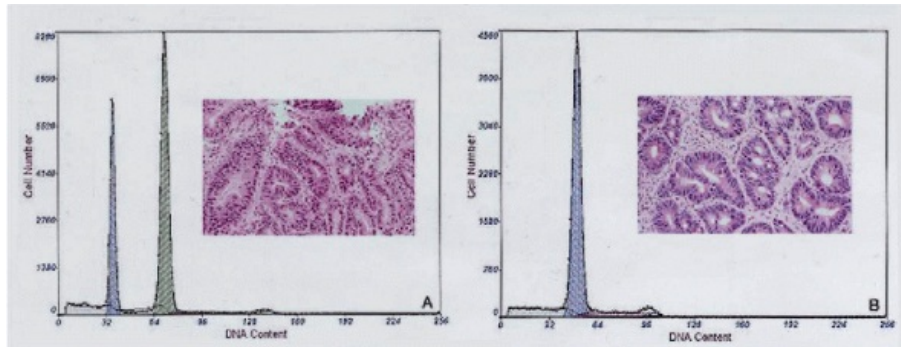

Figure 47-14 DNA analysis of Barrett's esophagus. *A,B.* Biopsies from two different sites of Barrett's esophagus in a 72-year-old physician, taken at the same procedure and interpreted as indefinite for dysplasia or low-grade dysplasia. DNA histogram of biopsy in *A* showed a near-tetraploid aneuploid population with low proliferative rate. DNA histogram of biopsy in *B* showed a normal diploid pattern. DNA histograms performed on biopsy tissue extracted from the paraffin blocks, DAPI stain. (Courtesy of Dr. Peter Rabinovitch, Seattle, WA.)

Oral Squamous Carcinoma

In a compelling, blinded image analysis study of the risk of oral cancer in patients with leukoplakia, Sudbø et al (2001) followed 150 patients for 4 to 165 months and found that only 3% of dysplastic leukoplakias with diploid DNA progressed to cancer, whereas 60% with tetraploid DNA and 84% with aneuploid DNA progressed to cancer. Further, the risk of progression was inversely related with time to malignant transformation. In a later report of 150 patients with oral leukoplakia, 5 of 103 with diploid, 16 of 20 with tetraploid, and 26 of 27 with aneuploid leukoplakia developed carcinoma over 4 to 237 months follow-up (Sudbø et al, 2004). The Sudbø studies were performed by image analysis of Feulgen-stained nuclei. The same strong prognostic significance of DNA ploidy has yet to be established for other squamous carcinomas of head and neck. For further comments, see Chapter 21.

Human Cancers With Probable Prognostic Significance of DNA Histograms

Carcinoma of the Breast

DNA Ploidy

In an early report by Atkin (1972), and subsequent studies of Caspersson et al (1983), Auer et al (1984), Erhardt et al (1986), Fallenius et al (1988), and others who measured DNA content of breast cancer cells by spectrophotometric absorption of the tumor cells on smears, the distribution of DNA measurements and modal values could be correlated with prognosis (see Chap. 29). Patients with diploid tumors had the best survival, aneuploid tumors had the poorest survival and tetraploid tumors were intermediate. Since then, breast cancer has been extensively studied by flow cytometry. Among the earliest reports by Olszewski et al (1981A, 1981B) and Raber et al (1982), DNA ploidy and

P.1727

S-phase fraction were correlated with tumor stage, grade and estrogen receptor expression. Bedrossian et al (1981) failed to show this correlation. These early studies were carried out on

fresh tumor tissue and there was no follow-up information on these patients.

Hedley et al (1984, 1987) and others (reviewed by Hedley, 1989) were able to undertake retrospective studies of archived, paraffin-embedded tissue from patients with known clinical follow-up. The majority of breast carcinomas proved to be aneuploid, in the range of 60% to 80% in most series, with about 10% multiploid. Most medullary carcinomas are high-grade tumors and aneuploid, whereas most tubular and colloid carcinomas are near-diploid, suggesting that DNA ploidy is correlated with tumor type. Ewers et al (1984) reported a much higher rate of recurrence for low stage (T1) aneuploid compared with diploid tumors. In a study with 10 years of follow-up, Ewers et al (1993) reported that DNA ploidy and low estrogen receptor levels were predictive of patients at risk of recurrent disease and reduced survival. Beerman et al (1990) reported that DNA ploidy correlated with tumor stage, while others found ploidy to be an independent prognostic variable with better overall and relapse-free survival for diploid compared with aneuploid carcinomas (Cornelisse et al, 1987; Kallioniemi, 1987). In a prospective study that received considerable attention at the time, Clark et al (1989) reported that favorable DNA ploidy and low S-phase fraction were predictors of disease-free and overall survival of patients with node negative breast cancer. Others suggested that reports of a more favorable course for patients with DNA diploid tumors, based on univariate analyses, lost independent prognostic significance in multivariate analyses (Dowle et al, 1987), and that DNA ploidy has limited clinical utility (Hedley et al, 1993). In a prospective study of fresh frozen breast cancer tissue from 1301 patients (Bergers et al, 1997), and another from 303 patients (Bracko et al, 2001), the favorable prognostic significance of diploid vs. nondiploid DNA values was confirmed in univariate analyses of both disease-free survival and overall survival. However, multivariate analyses of DNA ploidy added no additional prognostic power to lymph node status and tumor size. Thus, in my judgment, **because it is highly correlated with other known prognostic parameters, DNA ploidy of breast cancer has limited clinical value.**

S-Phase Fraction Analysis

The system of grading breast carcinomas most widely used today, or modifications of it, takes into account mitotic rate (Aaltomaa et al, 1992; Biesterfeld et al, 1995) as well as nuclear atypia and extent of tubule formation (Bloom and Richardson, 1957). The S-phase fraction or the proliferative fraction correlate well with mitotic counts (McDivitt et al, 1984; Bosari et al, 1992), with thymidine labeling (McDivitt et al, 1985; Meyer et al, 1988) and also (though not perfectly) with counts of cells expressing the nuclear proliferation associated antigen Ki 67 (Isola et al, 1990; Vielh et al, 1990; Keshgegian and Cnaan, 1995; MacGrogan et al, 1997). In carefully conducted studies of tumor cell proliferation, as judged by incorporation of tritiated thymidine, Meyer et al (1983, 1988), Gentili et al (1981), and Tubiana et al (1981) were able to show that increased DNA replication in fresh samples of human breast carcinoma was an independent marker of more aggressive behavior. These observations were confirmed by Clark et al (1989) and others (Hedley et al, 1987; Kallioniemi et al, 1988; Stal et al, 1989; Toikkanen et al, 1989; Lipponen et al, 1992; Witzig et al, 1994; Camplejohn et al, 1995). Similarly, immunohistologic studies of the proliferation associated nuclear antigens PCNA (Aaltomaa et al, 1992) and Ki67 (Sahin et al, 1991; Wintzer et al, 1991; Veronese et al, 1993) also had independent prognostic significance, and have been applied successfully to needle aspiration cytology smears (Dalquen et al, 1997). Thus, **tumor cell proliferation by any of a variety of measurement techniques is a significant independent prognostic marker.** The importance of these observations will grow as techniques are developed to obtain cells in sufficient number for flow

cytometry from stereotactic biopsies, fine-needle aspirates, and perhaps duct washings (see Chap. 29). Stoler et al (2002) demonstrated that close to 10,000 cytokeratin-positive cells are released into the saline holding freshly collected stereotactic biopsy cores of mammary carcinoma, whereas fewer cells were released from benign lesions.

Colorectal Carcinoma

The first prospective flow cytometry study of DNA measurements of colorectal carcinoma was in a series of 33 patients studied at Montefiore Medical Center. The patients were followed for up to 5 years and a remarkable difference was found in the clinical course of those with diploid vs. aneuploid tumors, regardless of stage of disease (Wolley et al, 1982). The patients with diploid tumors had fewer recurrences and lived longer, even in the presence of metastases. Unfortunately, there were too few patients to establish a statistical significance of this study. A second prospective study of 33 patients, followed for 3 years, failed to confirm that the patterns of metastasis or survival correlated with DNA ploidy (Melamed et al, 1986). A subsequent, much larger, prospective study of 176 patients showed no independent prognostic significance for DNA index, RNA index or proliferative fraction (Enker et al, 1991). However, in the special case of low stage, low-lying rectal carcinomas that were treated by local excision, Chang et al (1987) found that DNA aneuploidy predicted recurrence, though it did not predict survival.

A number of retrospective studies were carried out in succeeding years but, again, with conflicting findings. Two-thirds to three-fourths of colorectal carcinomas overall are aneuploid and there is a tendency to find more aneuploid tumors in high stage compared to stage 1 carcinomas. In studies by Armitage et al (1985), Kokal et al (1986), Scott et al (1987), and Risques et al (2001), DNA diploid values were associated with a more favorable prognosis. Banner et al (1985) and Jass et al (1989) reported that DNA ploidy was of significance in univariate analysis, but was correlated with other prognostic parameters and lost significance in multivariate analyses. Schutte et al (1987) initially reported DNA ploidy and proliferation to be of prognostic value in advanced stage colon cancer, but concluded later that

P.1728

significance was lost in multivariate analysis (Wiggers et al, 1988). Tang et al (1995) and Zarbo et al (1997) also concluded that DNA ploidy was not an independent predictor of survival. Finally, complicating matters even more, Hiddemann et al (1986) reported that DNA stemlines in colon carcinoma were heterogenous and could vary according to sampling. Similar observations on multiple tumor samples were reported by Wersto et al (1991). **Thus, while DNA ploidy appears to be of some prognostic significance, it adds little to the prognostic value of tumor stage and grade in fully developed colonic cancers. However, it may prove of value in assessing endoscopic biopsies when tumor stage is uncertain.** Tsushima et al (1987) also suggested that DNA ploidy may be of prognostic value in the case of patients undergoing resection of hepatic metastases of colorectal carcinoma. Survival of patients with aneuploid metastases was significantly shorter than of patients with diploid metastatic tumors.

Bauer and colleagues (1987) and a 1993 consensus review agreed that the **S-phase fraction had greater independent prognostic value than DNA index** (Bauer et al, 1993). Further study is needed to confirm these observations.

However, aneuploidy may serve as an indicator of malignant transformation in colonic polyps and in chronic inflammatory bowel disease. Aneuploidy has been observed in adenomatous, but not hyperplastic, polyps (van den Ingh et al, 1985; Weiss et al, 1985; Goh et

al, 1986; Quirke et al, 1986; Banner et al, 1987; Giaretti et al, 1988), and in ulcerative colitis (Hammarberg et al, 1984; Melville, 1988; Lofberg et al, 1990, 1992; Rubin, 1992), both known to be potentially precancerous conditions. Sciallero et al (1988) emphasized the association of aneuploidy in adenomatous polyps with a family history of colon carcinoma. For further comments on this topic, see Chapter 24.

Cutaneous Malignant Melanoma

DNA aneuploidy is found in about two-thirds to three-quarters of primary cutaneous malignant melanomas. In most retrospective studies of these tumors, DNA ploidy appears to correlate with tumor thickness and stage of disease and, with a few exceptions, with probability of recurrence and survival (Zaloudik et al, 1988). Hansson et al (1982) found that the great majority of metastatic melanomas were aneuploid and that patients with high S-phase fraction tumors (>10%) had significantly shorter survival than those with lower S-phase tumors. Similar observations pertaining to primary and metastatic melanomas were reported by Sondergaard et al (1983), von Roenn et al (1986), and Silver et al (1989). In the large series of 804 primary melanomas, Bartkowiak et al (1991) found that 43% of primary melanomas were nondiploid and 11% had high S-phase (>15%), which correlated with tumor progression and poor prognosis. Interestingly, at least some benign nevi ranging from three percent (von Roenn et al, 1986) to 25% (Sondergaard et al, 1983) were aneuploid, and Stenzinger et al (1984) observed that some congenital melanocytic nevi (4 out of 39) were aneuploid. Whether this indicates a premalignant state is unknown at this time. Long term prospective studies still are needed before we know whether DNA ploidy and/or S-phase fraction of melanotic neoplasms offers clinically useful prognostic information, and whether it justifies altering treatment that is currently based on clinical and pathologic criteria. For further comments on prognosis of malignant melanoma, see Chapter 34.

Carcinoma of Ovary

In retrospective studies of carcinoma of the ovary, DNA ploidy has been shown to be a major determinant of survival. It is correlated with histologic grade and stage and with expression of p53 (Skimisdottir, 2001). Aneuploid tumors, in general, are high grade and high stage, whereas low grade, low stage tumors are predominantly diploid (Friedlander et al, 1983). Survival rates of women with diploid and near diploid tumors were significantly better than those of women with aneuploid tumors (Hedley et al, 1985; Blumenfeld et al, 1987). As with carcinomas of other organs, tetraploid tumors have a somewhat more favorable prognosis than nontetraploid aneuploid tumors (Iversen, 1988). Multiploid carcinomas are more aggressive than tumors with a single aneuploid population. The S-phase fraction, like the mitotic index and other measures of proliferative activity, seems intuitively to be of prognostic significance and has been so reported (Volm et al, 1985; Kallioniemi et al, 1988; Kühn et al, 1989), but most tumors with a high S-phase fraction are also aneuploid.

Brenner tumors, which are benign, and the borderline epithelial ovarian tumors, which typically behave in a benign fashion, are predominantly diploid (Friedlander et al, 1984; Iversen et al, 1987; Trebeck et al, 1987; Kühn et al, 1989).

Thus, though there is still need for large, prospective, clinically correlated flow cytometry studies to unequivocally establish the prognostic significance of DNA ploidy and S-phase fraction, accumulated evidence suggests that these parameters may be of prognostic significance and correlate well with tumor grade and stage. For further comments on behavior of ovarian cancer, see Chapter 15.

Endometrial Carcinoma

While there are still few flow cytometry studies of endometrial carcinoma, the existing data, based on retrospective studies, are consistent with a better prognosis for diploid tumors with low proliferative fraction, compared with aneuploid tumors with high proliferative fraction (Geisinger et al, 1986; Iversen, 1986; Lindahl et al, 1987; Nordstrom et al, 1996; Kaleli et al, 1997; Susini, 1999; Mariani et al, 2000). In general, poorly differentiated tumors are aneuploid, whereas most diploid tumors are well-differentiated or intermediate grade endometrioid carcinomas. High stage tumors are predominantly aneuploid, implying more aggressive behavior. Most tumors responding to progestational therapy are DNA diploid. In patients with atypical adenomatous endometrial hyperplasia, the risk of developing endometrial carcinoma is greatest among those with endometrium having high S-phase fraction and/or aneuploidy (Lindahl et al, 1998; Eissa, 1997). Thus, as with ovarian cancer, the significance of DNA ploidy study is based, in large part, on a comparison with other known parameters of prognosis. A large, long term prospective

P.1729

study will be needed to confirm the retrospective studies. See also Chapter 13.

Bone and Soft Tissue Sarcomas

Most of the bone and soft tissue sarcomas that have been studied by flow cytometry have been aneuploid and there is general agreement that **virtually all high-grade osteosarcomas are aneuploid** (Kreicbergs et al, 1984; Helio et al, 1985; Mankin et al, 1985, 2002; Hiddemann et al, 1987; Xiang et al, 1987; Bauer et al, 1988; Look et al, 1988; el-Naggar et al, 1995; Berven, 2002). In a study of 168 osteosarcomas by Bauer et al (1988), only four low-grade paraosteal osteosarcomas were consistently diploid, and DNA ploidy successfully predicted the clinical course in 17 patients with diagnostically controversial tumors. In a prospective study of 26 patients, Look et al (1988) reported that osteosarcomas with near-diploid tumor stem lines had a favorable response to chemotherapy and improved survival when compared with tumors having hyperdiploid (aneuploid) stem lines.

Alho et al (1983) reported that patients with **chondrosarcomas** with diploid DNA had significantly longer survival than patients with aneuploid tumors. Similarly, **Ewing's sarcoma** with diploid DNA is reported to have a more favorable course than those that are aneuploid (Dierick, 1993; Perotti et al, 1998). On the other hand, Scott et al (1989) studied nine **giant cell tumors** of bone that developed metastases, and 8 that did not, and found no difference in DNA ploidy pattern. Simultaneous DNA/RNA measurements of bone tumors were carried out by el-Naggar et al (1995) who observed consistently high RNA in giant cell tumors, aneurysmal bone cysts and chondroblastomas.

DNA ploidy had no significant predictive value for **rhabdomyosarcoma** of children (Kilpatrick et al, 1994).

In a retrospective study of **gastric leiomyosarcomas**, Tsushima et al (1987) reported somewhat better prognosis for near-diploid, compared with aneuploid, tumors. However, aneuploid DNA was found in a small number of leiomyomas and in 7 of 20 leiomyoblastomas. Whether these would now be classified as GIST tumors (gastrointestinal stromal tumors), as discussed in Chapter 24, is impossible to say.

Nondiploid DNA patterns were found in several benign soft tissue spindle cell lesions by Agarwal et al (1991) and in some benign endocrine tumors (see below). Thus, **the finding of**

an aneuploid DNA population per se, while usually due to a malignant tumor, must be interpreted in the histologic context of the lesion examined. There still are too few studies of DNA ploidy in tumors of bone and soft tissues to draw any conclusions regarding diagnostic or prognostic significance. For further comments on prognosis of these tumors, see Chapters 35 and 36.

Human Cancers With Uncertain Prognostic Importance of DNA Histograms

Lung Carcinoma

Carcinomas of the lung, regardless of histologic type, are a group of diseases with unfavorable prognosis. Clinical outcome is highly correlated with stage of the disease. Only localized, non-small cell carcinomas (NSCC) have a reasonable possibility of cure following resection. Thus, flow cytometric measurements of DNA ploidy and proliferation have secondary importance, at best (see Chap. 20).

The early flow cytometry studies of patients with squamous cell carcinomas and adenocarcinomas that comprise the NSCC were reported to have a somewhat better survival if the tumors were diploid or near-diploid (Bunn et al, 1983; Volm et al, 1985, 1988). DNA aneuploidy correlated with higher stage and grade but evidence of independent significance was weak and controversial. Small cell carcinomas (SCC) are generally considered already metastatic when diagnosed and are treated as systemic disease by irradiation or chemotherapy, with near 100% mortality rate. Few SCC have been studied but Abe (1985) reported a somewhat better course for those that were diploid.

In the decade since the prior edition of this book, a number of multivariate analyses of DNA ploidy and proliferation in NSCC and SCC of lung were published. **Some authors reported adverse prognostic significance for aneuploid squamous and/or adenocarcinoma** (Zimmerman et al, 1987; Dazzi et al, 1990; Isobe et al, 1990; Sahin et al, 1990; Miyamoto et al, 1991; Rice et al, 1993; Yu et al, 1993; Salvati et al, 1994; Kolodziejewski et al, 1997; Muguerza et al, 1997; Pelletier et al, 2001), **while others found only questionable or no independent prognostic significance in DNA ploidy** (ten Velde et al, 1988; Carp et al, 1992; Filderman et al, 1992; Schmidt et al, 1992; Granone et al, 1993; Morkve et al, 1993; Visakorpi et al, 1995; Dalquen et al, 1997; Ikonen et al, 1999; Hofmann et al, 2001). Our own study of 93 radically resected, localized adenocarcinomas of lung showed no prognostic significance for DNA ploidy, fraction of aneuploid cells, or proliferative fraction (Cibas et al, 1989).

Other studies of **proliferation markers**, primarily S-phase fraction (SPF) or proliferative index (S + G₂M) or, in a few cases, bromodeoxyuridine labeling (BrdUrd), again yielded conflicting findings. High S-phase fraction, or other measure of proliferation, was an adverse prognostic marker for squamous and/or adenocarcinoma in reports by Dazzi et al (1990), Filderman et al (1992), Visakorpi et al (1995), Alvarez-Riesgo et al (1998), Volm and Koomagi (2000), and Pelletier et al (2001). Other observers reported questionable or no independent prognostic significance of these factors (ten Velde et al, 1988; Schmidt et al, 1992; Granone et al, 1993; Rice et al, 1993; Dalquen et al, 1997; Kolodziejewski et al, 1997; Ikonen et al, 1999; Hofmann et al, 2001). Dalquen et al (1997) found that **nuclear p53 expression**, a marker of malignant transformation, was strongly correlated with high S-phase fraction. Curiously, and contrary to other studies, Gasinska et al (1997) found that higher proliferation rates of NSCC, determined by BrdUrd labeling, were associated with better prognosis.

Small cell carcinoma was studied by Viren et al (1997) who found no prognostic value in either

DNA ploidy or S-phase fraction. Carey et al, who reported in 1992 that patients with DNA aneuploid SCC tumors have reduced 2-year survival compared with diploid or tetraploid tumors, were unable to confirm the initial observations in 1996.

In other applications, Cicconetti et al (1997) used dual

P.1730

parameter DNA/protein flow cytometry to identify epithelial cells among the leukocytes in bronchial wash specimens and thereby to increase sensitivity in detecting neoplastic cells. Ichinose et al (1991) suggested that metachronous lung cancers could be distinguished from metastases by DNA patterns.

Carcinoma of Uterine Cervix

Response to Radiotherapy

In their original cytophotometric studies of invasive carcinomas of the uterine cervix, Atkin and Richards (1962) found that **aneuploid/triploid tumors had a better response to radiotherapy than did diploid tumors**. These observations were later confirmed in a flow cytometry study of 348 patients by Dyson et al (1987) who found aneuploid tumors significantly more radioresponsive than diploid tumors, although DNA ploidy was not an indicator of a better prognosis. Thus, the rate of local recurrence of irradiated late stage tumors was **lower for aneuploid, compared with diploid tumors**. On the other hand, aneuploid tumors metastasized to distant sites at an earlier stage. With minor variations, the fundamental observations of Atkin and Richards were also confirmed by other investigators (Rutgers, 1986; Davis et al, 1989; Lutgens et al, 1994; Tang et al, 1995; Anton, 1997). Jakobsen and colleagues (1984, 1985, 1988) determined that aneuploid carcinomas of the cervix with a DNA index above 1.5 constituted a high-risk group with increased likelihood of nodal metastasis, higher recurrence rates and lower 10-year survival. However, Willen et al (1987) noted that DNA aneuploidy correlated with tumor grade and stage and later reported that it was the patients with high S-phase fraction tumors who had lower survival (Willen et al, 1993).

Some of the differences among investigators may be ascribed to technical factors. For example, Kimmig et al (1995) "gated out" stromal and other cells by using dual parameter DNA/cytokeratin flow cytometry and measured epithelial cells selectively, resulting in more tumors identified as aneuploid and more with high S-phase fraction.

Response to Surgical Treatment

Kenter et al (1990) found **no prognostic significance for DNA ploidy**. Jelen et al (1994), Lai et al (1993), and Connor et al (1993) found neither DNA ploidy nor S-phase fraction to have prognostic value. Kristensen et al (1995) also found no prognostic significance for DNA ploidy or S-phase fraction. However, Nguyen et al (1993) and Horn et al (2002) reported that early stage cervical carcinomas with high DNA index and high proliferative fraction (SPF) were a subgroup with less favorable outcome. Zanetta et al (1992) reviewed the Mayo Clinic cases and reported no significant survival difference between diploid and nondiploid early stage carcinomas, but diploid tumors with high proliferative fraction carried a significantly lower survival rate.

Other Studies

Strang et al (1987, 1991) carried out what is, perhaps, the most definitive **prospective study** in a population of 307 women with cervical carcinoma, followed for 4 to 84 months, and found

that **DNA ploidy yields little prognostic information** but that the prognostic impact of **S-phase fraction** was second only to stage.

Thus, **the possible significance of flow cytometry DNA measurements of uterine cervical squamous carcinoma is still uncertain. Present evidence suggests that S-phase fraction, but probably not DNA ploidy, may be of prognostic significance.**

However, because invasive cervical carcinomas are no longer commonly seen in major academic institutions, it has become increasingly difficult to validate this with additional statistically rigorous prospective studies. Measuring DNA ploidy and proliferative activity in squamous carcinoma in situ is more difficult but has been accomplished (Jakobsen et al, 1983; Hanselaar et al, 1988) and may provide new insights into the process of carcinogenesis and invasion. For further comments, see Chapters 11 and 18.

Adenocarcinoma of Cervix

Kaspar et al (1997) studied 29 patients with stage I, node-negative adenocarcinoma of cervix, of which 23 were diploid, and found no prognostic significance for DNA ploidy or proliferative activity. However, Magtibay et al (1999) analyzed 57 cases of adenocarcinoma, stage IB and IIA, of which 31 were aneuploid and 8 tetraploid, and found high proliferative index to have prognostic significance in node negative patients; DNA ploidy had no prognostic significance (see Chap. 12).

Squamous Carcinomas of Head and Neck, Other Than Oral Carcinoma

Studies of the squamous carcinomas of head and neck have yielded conflicting results. Goldsmith et al (1986, 1987) reported in a retrospective study that, **contrary to other tumors, aneuploid squamous carcinomas of the upper aerodigestive tract responded more favorably to treatment than did diploid carcinomas.** But, in a review of factors affecting the prognosis of laryngeal carcinoma, Danic et al (2000) found that DNA aneuploidy and high proliferative activity were both indicators of unfavorable prognosis and that proliferative activity remained significant in multivariate analysis. Myers et al (1999) also found better survival of patients with diploid, low S-phase laryngeal or pharyngeal carcinomas treated by surgery. Kokal et al (1988), who studied 76 patients with primary resectable squamous carcinoma of oral cavity, pharynx or larynx, found significantly decreased relapse-free and overall survival rates for DNA aneuploid tumors. Kokal concluded that **DNA content** was an independent, and the single most **important prognostic factor** in primary resectable carcinomas of head and neck. Walter et al (1991) found DNA aneuploid early stage laryngeal carcinomas more resistant to radiotherapy but Stern et al (1995) did not. Bourhis et al (1996) labeled S-phase cells with bromodeoxyuridine in vivo, and determined the labeling index, duration of S-phase and doubling time of squamous oropharyngeal carcinomas treated by irradiation. In a prospective study of 70 patients, neither DNA index nor any measure of proliferation was of prognostic value. Rua et al (1991) suggested that DNA ploidy was an independent parameter of prognosis for squamous laryngeal carcinoma,

P.1731

while Mohr et al (1992) found no correlation between flow cytometric data and prognosis for oral and pharyngeal carcinomas. **Thus, while the preponderance of evidence suggests that diploid, low proliferation tumors have a more favorable response to both surgical and radiotherapy, there is still no general consensus on the significance of these measurements in clinical practice.** One wonders why oral squamous cancers, discussed above, differ from other squamous cancers of the head and neck areas.

Renal Carcinoma and Wilms' Tumor

In early retrospective studies of renal carcinoma, Otto et al (1984) reported that only about 21% of patients with diploid tumors had metastases within a follow-up period of 1 to 4 years, compared with 89% for patients who had aneuploid tumors. In a study by Ljungberg et al (1986), surgical excision of metastases was of significant benefit in patients with diploid, compared with aneuploid, primary tumors. Rainwater et al (1987) reported increased probability of metastases and decreased long-term (10-year) survival for patients with aneuploid grade I and II clear cell carcinomas when compared with diploid tumors (37% vs. 62%). In a study of 59, stage I renal carcinomas Larsson (1994) concluded that DNA ploidy and S-phase fraction were of prognostic value. In other studies, DNA ploidy and/or proliferative fraction were found to be significant by some (Larsson et al, 1993; Ljungberg et al, 1996; del Vecchio et al, 1998; Di Silverio et al, 2000; Abou-Rebyeh et al, 2001) but not by others (Ekfors et al, 1987; Grignon et al, 1989; Currin et al, 1990; Nakano et al, 1993; Yu et al, 1993; Ciancio, 1995; Shameem et al, 1996; Tannapfel et al, 1996). **There is still no consensus with respect to the significance of DNA ploidy and proliferation fraction in renal cell carcinoma** (see Chap. 40).

In a study of DNA ploidy in **Wilms' tumors**, Rainwater et al (1987) found that patients with advanced stage disease (III/IV) and tetraploid tumors fared significantly worse than patients with diploid or aneuploid tumors.

Human Tumors Without Prognostic Significance of DNA Histograms

Thyroid Tumors

Endocrine tumors, in general, are characterized by the presence of polyploid and aneuploid cells but the presence of an aneuploid population does not necessarily signify malignant behavior. Nodular goiters from 15 of 81 patients studied by Castro et al (2001) and 11 of 108 patients by Mizukami et al (1992) were aneuploid. Greenebaum et al (1985), Joensuu et al (1986), and Czyz et al (1994) found that **many thyroid adenomas had aneuploid tumor cell populations. Conversely, many of the thyroid cancers are diploid**, particularly those that are well differentiated, including papillary, follicular and medullary carcinomas (Johannessen et al, 1981; Tangen et al, 1983; Joensuu et al, 1986; el-Naggar, 1990; Mizukami et al, 1992; Castro et al, 2001). Cusick et al (1991) found similar proportions of benign and malignant follicular neoplasms to be aneuploid. Hruban et al (1990) found that only 2 of 27 follicular adenomas and 3 of 11 follicular carcinomas were nondiploid and that DNA ploidy was of no prognostic value. Only Hay et al (1990) attached diagnostic significance to the DNA distribution in medullary carcinoma.

As part of a nationwide study of thyroid carcinomas in Iceland, Jonasson and Hrafnkelsson (1994) measured DNA ploidy in 424 tumors and found aneuploid populations in approximately 10% of papillary carcinomas, 24% of follicular carcinomas, 43% of medullary carcinomas, and 79% of anaplastic carcinomas. They also measured S-phase fraction, which was somewhat lower in papillary carcinoma than in other histologic classes, but **neither DNA ploidy nor S-phase fraction were of independent prognostic significance** (see Chap. 30).

Adrenal Tumors

Bowlby et al (1986) found all 16 adenomas of the adrenal cortex to be diploid and 5 of 6 cortical carcinomas aneuploid. In children with adrenocortical tumors, Taylor et al (1987) reported that seven unimodal (diploid) tumors from 5 patients were clinically benign after long follow-up,

whereas 4 of 5 tumors with abnormal DNA distribution metastasized. Venara et al (1998) reported that 9 of 16 adrenal cortical tumors in children were aneuploid and that the only 2 to metastasize were large and aneuploid. Camuto et al (1991) reported 21 of 22 adrenal carcinomas to be aneuploid. Cibas et al (1990) found aneuploid stem lines in 9 of 13 carcinomas and 6 of 30 adenomas. While DNA ploidy was highly correlated with tumor size and mitotic rate, there was no difference in survival of patients with aneuploid versus diploid tumors, and patients with aneuploid adenomas have remained alive and well.

Rainwater et al (1989) examined 20 benign and 6 malignant aldosterone-producing tumors. Only 3 of 6 malignant tumors were aneuploid, and they were the only patients to die of their tumor (the 3 other malignant tumors and 3 of 20 benign tumors were tetraploid or polyploid). Shono et al (2000) studied 67 hormone-secreting cortical adenomas and found 8 to be aneuploid and 27 tetraploid. For further comments, see Chapter 40.

Pheochromocytomas are difficult or impossible to classify as malignant or benign on histologic grounds alone, and prognostic significance has been sought in flow cytometric studies of DNA ploidy and proliferation. In an early study by Amberson et al (1987), 13 of 19 clinically benign pheochromocytomas had tetraploid or aneuploid DNA. More recently, Nativ et al (1992) reported that one-third each of 184 pheochromocytomas and paragangliomas were diploid, tetraploid and aneuploid. All patients with metastases had tetraploid or aneuploid tumors, and the 12 patients who died of pheochromocytoma had abnormal DNA ploidy. None of 64 patients with diploid tumors died of their tumor. All 7 malignant tumors in the study by Pang and Tsao (1993) had tetraploid or aneuploid DNA populations, as did 16 of 72 benign tumors. In a study of 62 patients followed for a minimum of 10 years, Hosaka et al (1986) reported that all 18 tumors with diploid DNA followed a benign clinical course, while 8 of 26 with tetraploid/polyploid tumors and 7 of 18 with aneuploid tumors were malignant. In a study of 36 patients, Garcia-Escudero et al (2001) also concluded that diploid DNA is a marker of good prognosis,

P.1732

though not all nondiploid tumors are necessarily malignant. Thus, with rare exceptions (Brown et al, 1999), there appears to be a **consensus that diploid DNA predicts a benign course, whereas non-diploid tumors may be either benign or malignant.**

Neuroblastoma

Look et al (1984) reported that infants with hyperdiploid neuroblastoma responded better to chemotherapy than did infants with diploid tumors. Subsequently, Gansler et al (1986), Naito et al (1991), Huddart et al (1993), and Kusafuka et al (1994) also reported that patients with diploid neuroblastomas had a less favorable prognosis and suggested the consideration of more aggressive treatment for this group of tumors.

Pituitary Tumors

In a series of reports, Anniko et al (1984, 1985) examined tumor tissue from 62 patients with pituitary adenomas and found approximately half to be nondiploid. Aneuploidy was lower in non-hormone-secreting tumors (22%) and highest in prolactinomas (70%). Similar findings were reported by Ludecke et al (1985), Hulting et al (1989), and Bononi et al (1994). Chae et al (1996) studied DNA ploidy and proliferative activity in 16 recurrent versus 17 nonrecurrent pituitary adenomas and found no significant differences. Fornas et al (1996) reported that high proliferative index (PCNA) distinguished pituitary hyperplasia from normal.

Gastric Carcinomas

The prognosis for gastric carcinoma is highly dependent on stage of the disease (see Chap. 24). While the Japanese have shown that very early stage carcinomas, still confined to the gastric mucosa, have a favorable outlook, the prognosis for more advanced carcinomas is dismal, and overall 5-year survival is an estimated 21% (Greenlee et al, 2001). In fully developed tumors, the rate of aneuploidy varies from 50% to 75%, with a tendency for more advanced carcinomas to be aneuploid (Candel et al, 1994; Sasaki et al, 1999). Whether DNA ploidy or proliferation are independent prognostic parameters still is controversial, perhaps in part because measurements can vary, depending on sampling. Thus, DNA ploidy has been reported to have independent prognostic value by some investigators (Yonemura, 1990; Tsushima et al, 1992; Flyger et al, 1995; Russo et al, 2001), particularly for resectable and potentially curable tumors (Danesi et al, 2000), but of borderline or no prognostic significance by others (Filipe et al, 1991; Candel et al, 1994; Omejc et al, 1997; Esteban et al, 1999).

S-phase fraction (SPF), proliferative index (S + G₂M) and bromodeoxyuridine (BrdUrd) labeling have been used to determine whether proliferation is of prognostic value, and results are again inconsistent. Russo et al (2001) found SPF to be significant, as did Lee et al (1999), whereas Filipe et al (1991), Esteban et al (1999), and Danesi et al (2000) did not. BrdUrd labeling is more accurate than S-phase calculations to determine proliferation and Ohyama et al (1990) and Sandler et al (2001) reported that it did have independent prognostic significance.

Odegaard et al (1987) reported aneuploidy in the uninvolved mucosa of patients with aneuploid gastric carcinoma and increased proliferative index in the uninvolved mucosa, accompanying both aneuploid and diploid carcinomas. None of 9 gastric polyps were aneuploid. Macartney and Camplejohn (1986) found DNA aneuploidy in 5 of 7 cases with severe dysplasia, but not in regenerative changes.

Evidence that DNA ploidy or proliferative markers are of prognostic value in gastric carcinoma is still inconclusive.

PRECANCEROUS EPITHELIAL LESIONS

As noted, not all malignant tumors are aneuploid and not all aneuploid tumors are malignant. While genetic abnormalities, by definition, are responsible for neoplastic transformation, they may involve translocations, inversions, deletions or amplifications that do not alter the total content of DNA or are too small to be measured. It is of interest that at least some precancerous epithelial lesions are reported to have populations of aneuploid cells. These include oral leukoplakia, discussed above, and uterine cervical intraepithelial neoplasms (see Chap. 11). Not surprisingly, the high-grade cervical squamous intraepithelial lesions are more frequently aneuploid than are low grade lesions (Jakobsen et al, 1983). Aneuploidy has been reported also in carcinoma in situ of skin (Newton et al, 1986), larynx (Bjelkenkrantz et al, 1983), esophagus (see above), stomach (Macartney and Camplejohn, 1986) and colon (Hammarberg et al, 1984; Petrova et al, 1986; Quirke et al, 1986). Carcinomas can arise from epithelium in which there are presumed, but nonmeasurable, changes in DNA, as has been demonstrated by Hanselaar et al (1988), who observed invasive carcinomas of the cervix arising from diploid precancerous lesions.

HEMATOLOGY

Automated Blood Counts

Automated blood cell counts are responsible for the vast majority of clinical applications of flow cytometry and, except when some abnormality is encountered requiring visual review, they have entirely replaced the manual blood cell count. Less frequent, but more critical, is the role that flow cytometry plays in the classification of leukemias and lymphomas, which now incorporates antigen expression (immunophenotyping) as a reflection of cell differentiation (see below).

The red blood cell count is essentially the same as the total cell count of whole blood. This is because the ratio of red to white cells is 1,000:1 and the presence of 0.1% white cells can be ignored. Red blood cell parameters, that is, the distributions of red cell size and shape, are measured by light scatter of the cells. Hemoglobin content was initially measured by absorption of light at 420 nm. However, this required a research flow cytometer with a near UV light source. An alternative approach, better suited to clinical instruments, is to swell the red cells to a spherical shape in hypotonic medium and measure light scatter at two different nonoverlapping forward angles (e.g., 2.5° to 3.5° and 5° to 15°). Red cell volume and internal density (i.e., hemoglobin content) can be calculated from these light scatter

P.1733

measurements. Immature red blood cells, which contain remnants of RNA (reticulocytes), are identified by staining for RNA with fluorescing dyes (e.g., thiazole orange) or absorbing dyes (e.g., new methylene blue).

Differential peripheral white blood cell counts are based primarily on differences in the light scatter properties of the major subsets of nucleated blood cells, first reported by Salzman et al (1975). It is not necessary to stain the cells, but it is necessary to lyse red blood cells. Then, by plotting forward angle (0.5° to 3.0°) light scatter, which is a measure of cell size, against right angle (90°) scatter, which depends on cytoplasmic granularity, it is possible to distinguish and separately identify and count granulocytes, lymphocytes, monocytes, eosinophils and basophils (see Fig. 47-5), with discrimination improved subsequently by using polarized light. At least a small proportion of the cells present are normal lymphocytes and these serve as an internal control. The total white cell count is determined by counts of a known volume of blood. An abnormal total or differential count, or the presence of immature cells with different light scatter properties, signal the need for visual microscopy.

Platelets range from 1 to 5 µm in size and can be identified in whole blood by 2-dimensional plots of forward scatter vs. immunofluorescence staining with an antibody to platelet glycoproteins IIb/IIIa (e.g., CD41). Because platelets are so small, diluents and reagents must be particle free. It is important to minimize handling during collection and processing to avoid activation and clumping of platelets.

Analysis of Lymphomas and Leukemias

Some of the **lymphomas and leukemias are characterized by aneuploid DNA** content (Look et al, 1982), which has been used to determine minimal residual disease (Nowak et al, 1997), and also to examine spinal fluid for meningeal involvement (Redner et al, 1984, 1986). The **classification of most hemopoietic neoplasms is by a combination of antigen expression and morphology, chromosomal karyotype and molecular genetics**. The principal clusters of differentiation present on the surfaces of leukocytes are listed in Table 5-1 in Chapter 5. Flow cytometry is essential for determination of antigen expression (see Chap. 31).

TABLE 47-6 SPECTRAL CHARACTERISTICS OF FLUOROCHROMES COMMONLY

USED FOR LABELING ANTIBODIES^a

Dye	Excitation Maximum	Emission
Fluorescein isothiocyanate (FITC) ^b	490 nm	520 nm
Phycoerythrin (PE)	480-560 nm	578 nm
Per CP	550 nm	575 nm

^a Other fluorochromes that are excited in the red (Texas Red, Cy3, Cy5, Phycocyanin, XRITC) have been designed to be used with FITC and PE in a three-color system. They are excited either directly by a krypton or HeNe laser in a dual laser instrument or by energy transfer (Phycoerythrin-Allophycocyanin, Phycoerythrin-Texas red) from a blue-excited dye (PE).

^b FITC is also an excellent protein stain.

In most cases, as already indicated, there are at least 4 measurements of each cell: two scatter and at least two fluorescence measurements. These data can be analyzed by the same statistical algorithms that are used to analyze the multidimensional data of high resolution image analysis (see Chap. 46). However, a much simpler approach is commonly taken, beginning with two dimensional scattergrams of forward vs. right angle (90°) light scatter (RALS) and antibody to CD45 (leukocyte common antigen) vs. RALS. The antibodies are labelled with fluorochromes with various excitation maxima (Table 47-6). The normal cellular components are represented by clusters of dots in distinctive locations (Fig. 47-15). Blasts in peripheral blood, marrow or lymph node would be represented by dots in a unique location; more mature leukemic cells would have measurements close to, or superimposed on, normal populations. The cells of interest, whether blasts or more mature, as determined by light microscopy, are **selected (gated)** in these initial scattergrams and the gated population is then viewed in a sequence of 2-dimensional scattergrams of different antibody combinations. In this way, the antigenic features of interest are measured on a defined population of cells. In moving from one scattergram to the next, it is convenient to color the dots representing the selected population and, if the relationships between several different populations are of interest, they can each be given a different color.

To classify a suspected lymphoma or leukemia, it is typically necessary to determine which of as many as 20 or more different antigens are expressed by the cells of the suspect population (Table 47-7). Suspensions of unfixed, viable cells from blood, bone marrow or lymph nodes are stained usually in sets of two antibodies against two different antigens (it is technically feasible to stain with as many as six different antibodies simultaneously). The antibodies are labeled with fluorescent dyes of different wavelengths, listed in Table 47-6. Two examples of such analyses are illustrated in Figures 47-16 and 47-17.

Once the panels of immunocytologic expression markers characteristic of a leukemic population are determined, they can be used to determine the presence or absence of minimal residual

disease in marrow during, or following, treatment.

P.1734

Stacchini et al (2003) found that flow cytometry (FCM) and morphologic evidence of minimum residual disease correlated in 84% of cases. In 25 of 210 specimens with biopsy evidence of minimum residual disease, the FCM panel was negative, because of myelofibrosis and scanty aspirate. In five cases, residual disease was detected by FCM but leukemic cells were too few to be identified by conventional microscopy. The interested reader is referred to Chapter 31 and any of several monographs dealing with this topic in detail (Laerum and Bjerknes, 1992; Stewart and Nicholson, 2000; Jaffe et al, 2001; Keren et al, 2001; Nguyen et al, 2003).

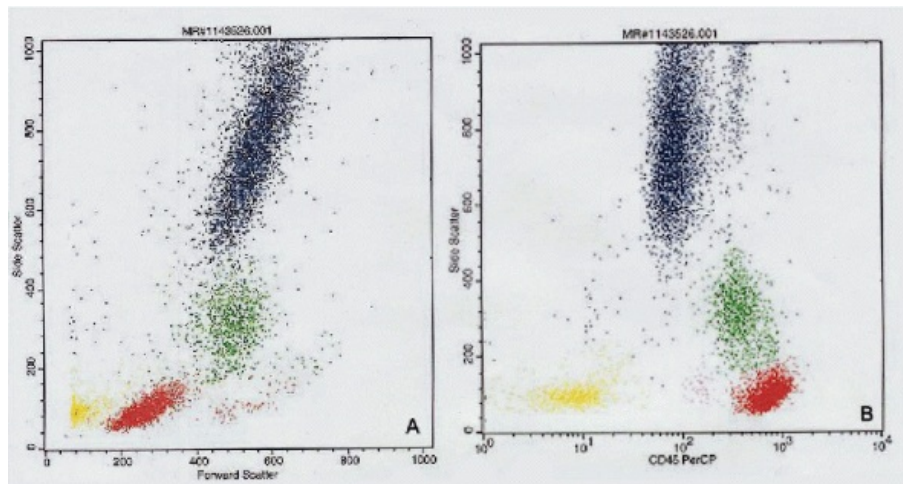

Figure 47-15 Two-dimensional flow cytometric scattergrams of normal peripheral blood. *A.* Forward (2° - 5°) versus side (90°) light scatter. Lymphocytes (red) are small with little cytoplasm and have low forward and low side scatter. Monocytes (green) are larger, have more cytoplasm, and greater forward and side scatter. Granulocytes (blue) are about the size of monocytes but have more granular cytoplasm and much greater side scatter. *B.* CD45 antibody expression vs side scatter. Cell populations as above. Note that lymphocytes strongly express CD45. The pale yellow cluster is made up of red blood cells and debris.

NEW HORIZONS

Over the last several years, a remarkable number of innovative cytometric techniques were developed for research applications in cell biology. Many have yet to find clinical laboratory application, but the research process is under way to define and measure cell parameters of potential clinical value. **Flow cytometry crossmatching for transplantation of solid organs** is one such example (Bray, 1994). It proved to be the most sensitive method for detecting alloantibodies and is now an invaluable aid in the selection of organ recipients. Indirect immunofluorescence is used to detect alloantibody in serum of the recipient that has bound to donor cells after incubation. A positive test (**bound antibody**) is an indicator of antibodies to donor cells that will result in transplant rejection.

Flow cytometry assays for **simultaneous measurement of DNA and RNA** were developed by Darzynkiewicz et al (1976, 1980, 1994) and Traganos et al (1977) based on differences in fluorescence emission of the metachromatic dye acridine orange when intercalated into double

stranded DNA (green) versus binding to single stranded RNA (red). To study the chromatin structure of whole cells, Darzynkiewicz et al (1976, 1979) removed RNA and used acridine orange to measure extent of single-stranded versus native double-stranded DNA in acid or heat-treated cells. Differences in resistance to denaturation distinguished diploid G₀ from G₁ cells and tetraploid G₂ from mitotic cells with the same DNA content (Fig. 47-18). Evenson et al (1980) used this same technique to demonstrate that subfertile men (and animals) had abnormal sperm chromatin manifested by diminished resistance to denaturation (Fig. 47-19). The technique also proved of value in monitoring the effects of toxic agents or irradiation on germ cells.

Flow cytometry assays have been developed for detection of specific mRNA species (Belloc et al, 1994), micronuclei assays for irradiation or chemical toxicity (Nusse et al, 1992, 1994; Miller et al, 1993; Smolewski et al, 2001), chromosome flow karyotyping (Carrano et al, 1979; Gray et al, 1987), detection of malarial and other parasites or viruses (van Vianen et al, 1993), detection of microorganisms in environmental samples, flow cytometry of algae and plant

P.1735

cells and other applications (see summaries by Darzynkiewicz et al, 1994; Bauer et al, 1993; Shapiro, 1995). A variety of soluble analytes also can be detected and quantified by flow cytometry using antibody-coated microspheres to capture the analyte, followed by a fluorescent anti-analyte antibody.

TABLE 47-7 FLOW CYTOMETRY ANTIBODY GROUPS FOR CELL TYPE CLASSIFICATION IN LYMPHOMA/LEUKEMIA

Hematopoietic stem cells and early differentiation markers: CD34, CD117, TdT, CD1a

B Cell

Precursor B-cell acute lymphocytic leukemia: CD19, CD10, TdT, cCD22, cells express either kappa or lambda, CD34⁺, CD117⁻

Normal B-cell precursors (hematogones): CD19, CD10, TdT, very low side-scatter

Normal mature B cells: CD19, CD20, CD22, and polyclonal mixture of cells expressing kappa and lambda

Neoplastic mature B cells: CD19, CD20, CD22, and monoclonal cells expressing either kappa or lambda

Chronic lymphocytic leukemia/small lymphocytic lymphoma: CD19, CD20, CD5, CD23

T Cell

T-cell precursors: CD2, CD7, CD3, CD1a, TdT, cells may express both CD4 and

CD8

Normal mature T cells: CD3, CD2, CD5, CD7, and either CD4 or CD8

Neoplastic mature T cells: CD3, CD2, CD5, CD7, and either coexpressing CD4 and CD8, negative for both, or a mix of coexpressing and negative cells

Myeloid

Myeloid precursors: CD13, CD33, CD117, CD34

Myelocyte markers: CD13, CD33, CD11b, CD15, CD16, HLA-DR, myeloperoxidase-positive

Acute (M3) myelocytic leukemia: CD13, CD33, other markers that are negative or weak include CD34, HLA-DR, CD11b, CD15, CD16

Other

Monocyte markers: CD14, CD33, CD64

Erythroid precursors: CD71 (transferrin receptor), glycophorin

NK cells: CD16, CD56, CD57

Plasma cell markers: CD38, CD138, CD56, cytoplasmic kappa or lambda

Megakaryocyte markers: CD41, CD42, CD61

Activation markers: HLA-DR, CD25, CD30, CD38

Mantle cell leukemia: bright CD20 (>CD19), CD5, CD23⁻, bright kappa or lambda, cyclin D₁

Hairy cell leukemia: CD20, CD25, CD11c, CD103, FMC 7

This table may give the reader an overview of the value of multiparameter antigenic expression in classification of leukemias and lymphomas. See also Chapter 31.

Examples of the many functional attributes and/or constituents of living cells that can be quantified by flow cytometry include live cell measurements of membrane potential, intracellular pH, intracellular calcium ion, mitochondrial function, lysosomal proton pump function, drug efflux (multidrug resistance) (Krishan et al, 1997), phagocytosis and oxidative burst, activity of various proteases, enzyme kinetics and other kinetic studies.

At the single molecular level, Goodwin et al (1993) a decade ago proposed that sizing of fluorescently labeled DNA fragments was possible by flow cytometry. Development of single photon counting photodiode detectors greatly increased sensitivity of fluorescence measurements and with more highly efficient DNA binding fluorescent dyes (e.g., Molecular Probes' Sytox-orange), flow cytometry may soon rival gel electrophoresis for DNA fragment size analysis (Yan et al, 2000). Kim and associates (1999) at the Los Alamos National Laboratory demonstrated the feasibility of rapidly typing bacterial species by flow cytometry assays of restriction fragment length polymorphisms (RFLP).

For a detailed overview of new developments in flow cytometry, the reader is referred to the excellent monograph edited by Darzynkiewicz, Robinson, and Crissman (2001).

LASER SCANNING CYTOMETRY

One of the criticisms often levied against flow cytometry is that it is not possible to correlate a specific measurement with the corresponding cell. Once measured, the cell is lost, except by cell sorting, which segregates for further analysis a class of cells, rather than single cells matching single measurements. So far, the efforts to develop methods of visualizing cells in flow have been unsuccessful.

Another approach was taken by Kametsky and Kametsky (1991) who developed an instrument capable of performing flow cytometric types of measurements on individual cells placed on microscopic slides. The same cells can be recalled for repeat measurements with different stains or excitation sources. The measurements can be correlated directly with the conventional morphologic criteria on a cell by cell basis.

The laser scanning cytometer or LSC (CompuCyte Corporation, Cambridge, MA) is a microscope-based instrument (Fig. 47-20). The cells or tissues to be examined on a glass slide are placed on a computer controlled stage of the microscope. Excitation through an epi-illumination port of the microscope is by a laser beam focused to a 2.5 μm spot (at 40 \times objective) that is reflected by a mirror oscillating at 350 Hz to form an excitation line measuring 300 μm in length in the y-axis. The cells or tissue on a slide move through this line in the x-axis of a motorized stage at 0.5 μm steps for each laser scan. The x,y position of the target is recorded with each measurement. The instrument diagramed in Figure 47-20 has two excitation laser light sources. Newer instruments are equipped with three different excitation beams: a blue argon ion laser, a red helium neon laser, and a violet laser. Forward angle light scatter is imaged by the condenser and collected by a sub-stage solid state sensor. Fluorescences emitted by the specimen are collected by the objective lens and reflected through a series of dichroic mirrors and filters that separate it into specific wavelength ranges to be recorded by as many as six different, appropriately filtered photomultipliers. Some of the fluorescence emission can be directed to a CCD color camera for imaging. Cells can be selected for visualization or photography by fluorescence or may be retained and examined by bright field optics. An instrument, based on the same principles, has been developed to carry out physiologic and pharmacologic studies of cells in tissue culture wells.

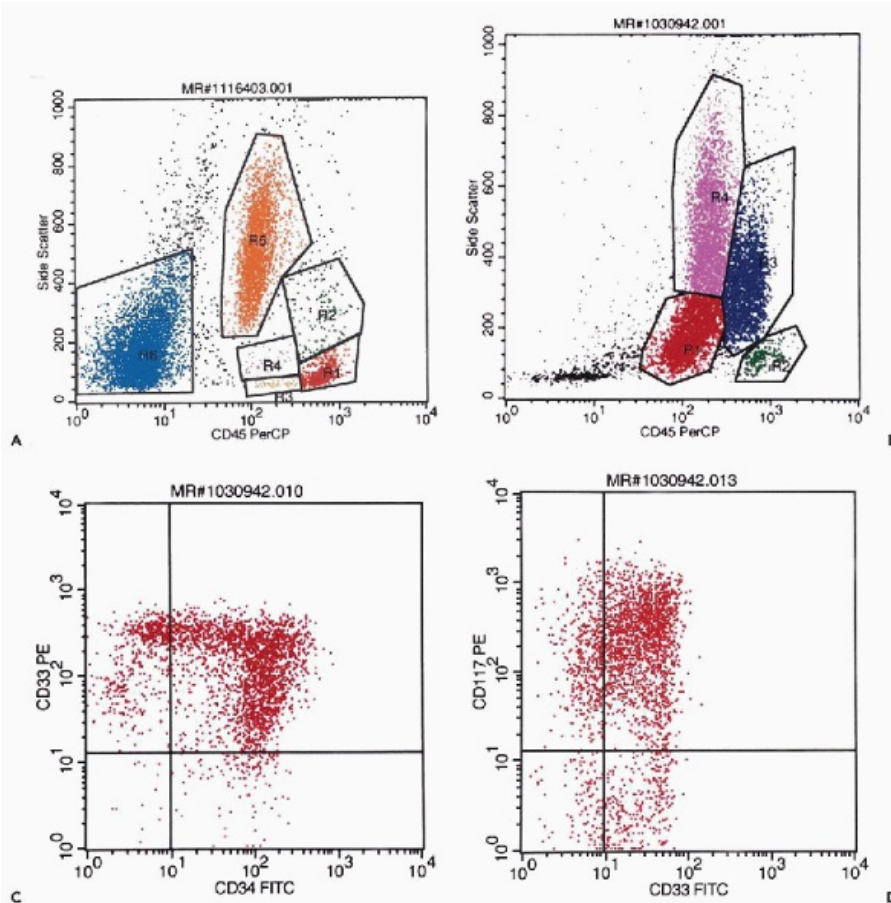

Figure 47-16 Flow cytometric scattergrams of bone marrow, normal and acute myelogenous leukemia. *A.* Normal bone marrow, CD45 vs. side (90°) light scatter. R₁ (red), lymphocytes; R₂ (green), monocytes; R₃, hematogones (immature cells); R₄, blasts; R₅ (orange), granulocytes; R₆ (blue), red cells and debris. *B.* Bone marrow of a 55-year-old woman with acute myelogenous leukemia. The population, R₁ (red), is in the location of blasts and continuous with granulocytes (R₄). It is gated for study of antigen expression in *C* and *D*. The gated population expresses CD33, a myeloid marker, and co-expresses two markers for blast cells, CD34 in *C* and CD117 in *D*.

P.1737

Figure 47-17 Flow cytometric scattergrams of pleural fluid with diffuse large B cell lymphoma. *A.* Each of the several populations present in the fluid was separately gated. *B.* One of the selected populations expressed B lymphocyte markers (CD19, CD20), and an activation marker (CD10). *C,D.* Show that the selected cell populations was monoclonal (kappa positive and lambda negative). In this case, cytologic suspicion of lymphoma could be conclusively confirmed by flow cytometry.

The multiple measured properties of each cell are recorded in list mode by computer software that defines the nuclear and cytoplasmic contours. The properties typically derived include: forward light scatter, area of the cell and/or nucleus, perimeter length of cell or nucleus (in micrometers), peak and integrated fluorescence at each wavelength measured for the whole cell, nucleus, or selected subcellular components, *x,y* coordinates locating the cell on the slide, time of measurement, and neighboring (background) fluorescence. Configuring algorithms can be set to exclude (threshold out) overlapping cells, cell clusters, and cellular

P.1738

debris. Data are presented graphically in the same way as in flow cytometry. As noted above, the cells can be retained after initial measurements, relocated by their *x,y* coordinates, and new features recorded for each cell in the list mode table. If desired, the cells can be relocated and visualized (Fig. 47-21). In some cases, the intensity of immunocytologic staining is of interest as, for example, in expression of receptors, and can be precisely quantified (Fig. 47-22).

Figure 47-18 DNA denaturation in the cell cycle. Differences in resistance to denaturation plotted against total DNA content distinguish diploid G₁ from G₀ cells and tetraploid G₂ from mitotic cells. (Courtesy of Z. Darzynkiewicz, New York Medical College, Valhalla, NY.)

The instrument has been described in more detail by Kamentsky et al (1997, 2001), with an assessment of its potential clinical applications by Darzynkiewicz et al (1999) and Tarnok and Gerstner (2002). The manufacturer maintains a website with a bibliography of scientific publications using the instrument (www.compucyte.com).

Figure 47-19 Sperm denaturation. *A.* Sperm from a normally fertile male resist heat denaturation and fluoresce green when stained with acridine orange. *B.* Sperm from a subfertile male lose resistance to heat denaturation and fluoresce red when stained with acridine orange. Measurements of red vs. red + green fluorescence are made by flow cytometry and give a quantitative parameter of fertility for sometimes normal-appearing sperm. (Courtesy of Dr. D. Evenson, South Dakota State University, Brookings, SD.)

The instrument offers a number of other advantages. Small samples with scant cellularity, such as spinal fluid for example, can be measured without loss of cells. Multistep staining processes can be carried out without loss of cells and with minimal volumes of sometimes expensive reagents. For cells emitting low intensity fluorescence signals, sensitivity can be increased by re-scanning and summing signal measurements. Since the cells are retained on the slide after completion of measurements and their location is known, they can easily be rescanned at selected time intervals to determine the kinetics of enzymatic or other intracellular processes. Morphologic features of each cell can be measured and recorded. Subcellular components that cannot be measured by flow cytometry are measurable by laser scanning cytometry. An example of this is shown in Figure 47-23, in which a deletion of one chromosome 8 was demonstrated in human bladder cancer cells by fluorescence in situ hybridization or FISH probes of that chromosome. Selected cellular products can be followed as they move from one to another compartment of the cell and measurements can be carried out on cells in histologic sections (see below). Measurement rates up to 5,000 cells/min are slower than by flow cytometry, but adequate for most purposes.

Fluorescence measurements can be localized specifically to cell membrane, cell cytoplasm, nucleus, or nucleolus. By sequential measurements on the same cell over time, it is possible to trace the movements of selected cellular constituents from one cellular compartment to another (Deptala et al, 1998; Gorczyca et al, 2001; Juan and Cordon-Cardo, 2001; Kakino et al, 1996). Gorczyca et al (2001) used the morphometric capability of the LSC to quantify number and size of nucleoli and expression of the nucleolar protein, nucleolin, in mitogenically stimulated lymphocytes. These authors were also able to demonstrate translocation of nucleolin from the nucleolus to nucleoplasm as the cells progressed through the cycle and into the next cycle. Bedner et al (2000) demonstrated translocation of the proapoptotic

P.1739

protein Bax into mitochondria to activate caspases at initiation of apoptosis (see Chap. 6). The imaging and localization feature, and high sensitivity of the instrument, also has been used to identify and count FISH probe spots in interphase nuclei and metaphase spreads (Kamentsky et al, 1997; Kobayashi et al, 2000).

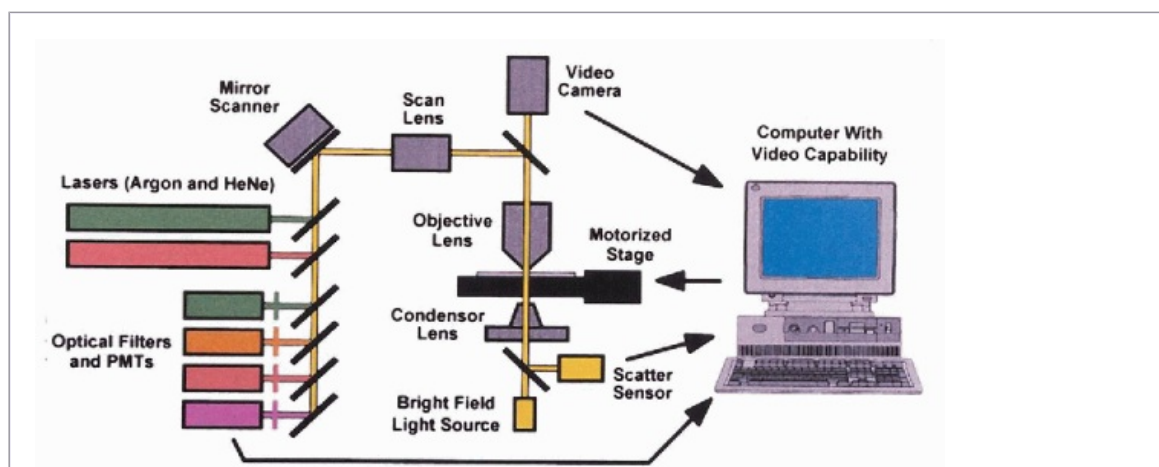

Figure 47-20 Laser scanning cytometer (LSC). Diagrammatic representation of the instrument showing dual laser excitation beams (argon ion, helium neon), each focused to a 2.5- μ m spot, forming a scan line in the y-axis of the slide. With each scan, the slide is

moved 0.5 μm in the x-axis. The fluorescence generated by each cell is collected back through the objective lens of the microscope, passed through mirrors and filters to photomultipliers where it is converted to electronic signals that are analyzed and displayed by computer.

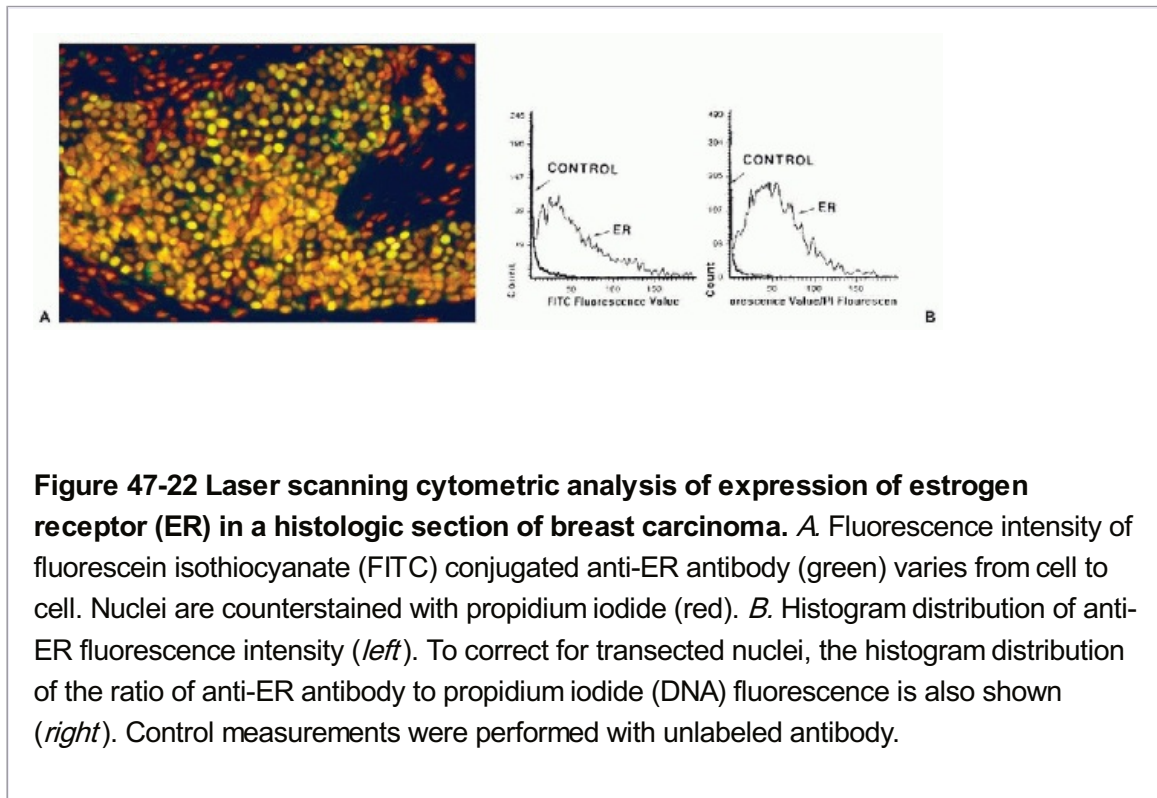

Figure 47-21 Laser scanning cytometric analysis of cytology imprint of carcinoma to quantify apoptosis. Apoptotic cells were identified by labeling DNA strand breaks, as described in legend to Figure 47-13. The cells were then restained with an anti-cytokeratin antibody to distinguish positive carcinoma cells from negative stromal and inflammatory cells. The relocated apoptotic cells could then be shown to be cytokeratin-positive by LSC and confirmed as carcinoma cells on visual examination.

Clatch et al (1997) used LSC to measure DNA distribution of breast cancer cells in aspiration biopsy (FNA) specimens, selected by expression of cytokeratins, and to immunophenotype hemopoietic specimens. Others have studied cytology specimens of sputum (Woltmann et al, 1999) and urinary sediment (Kawamura et al, 2000; Wojcik, 2001). Gorczyca et al (1997, 2001) made use of the LSC to quantify expression of various cellular antigens in cytologic specimens and histologic sections of a number of human solid tumors. The measurements were objective, quantitative and reproducible, and yielded histograms of the intensity of fluorescence per cell, as well as percent of positive cells. In addition to DNA measurements, which had a CV $\leq 4\%$, measurements included cyclin B₁, apoptotic and proliferating cells, and estrogen and progesterone receptors in breast cancer. Clatch and his associates (1998, 2001) have used the LSC for immunophenotyping hemopoietic neoplasms and specimens of carcinomas obtained by FNA (1997). Gerstner et al (2000) used LSC for immunophenotyping of peripheral blood in neonates.

Laser scanning cytometry is particularly useful for examinations of fine needle aspirates (FNA), in which there

are very limited numbers of cells, and close correlation of cytometry with cell morphology is helpful. It also makes possible the cytometry of select, small portions of tissue in paraffin blocks, excluding unwanted extraneous tissues (Kamiya et al, 1999). Other applications of the LSC include the micronuclei assay for monitoring nucleotoxic effects of irradiation or chemical mutagenic agents (Smolewski, 2001; Styles, 2001), time resolved kinetic measurements of intracellular enzymes (Bedner et al, 1998), or dissociation rates of DNA-fluorochrome complexes. Li and Darzynkiewicz (1999) emphasize the merge feature of LSC, permitting the same cells to be measured for certain attributes, when alive, and other attributes after fixation or permeabilization.

In summary, laser scanning cytometry offers the cytologist an opportunity to correlate cell classification and morphology by visual microscopy with measures of cellular constituents and functional attributes of potential prognostic significance, and to do so with sparsely cellular specimens.

Figure 47-23 Fluorescence in situ hybridization (FISH). A. An example of the FISH

technique. The centromere of chromosome 7 is labeled in green in the cells of a gastric carcinoma. The nucleus is counterstained by red fluorescing propidium iodide. There are two chromosomes 7 in three cells that are in G1 phase of the cycle and four chromosomes in one cell in G2 phase. *B.* Pseudo-three dimensional histogram of laser scanning cytometry (LSC) counts of a FISH probe to chromosome 8 in cells of a bladder carcinoma. On the x-axis (*left*), there is a single probe in most of the tumor cells, indicating that one chromosome 8 is deleted. The benign cells present (*center*) have two chromosomes 8. There are a few cells with three spots as a result of nonspecific (minor) binding sites. The cells were counterstained with propidium iodide for total nuclear DNA which is represented on the y-axis and increases as the cells progress through S-phase.

Appendix: Flow Cytometry Techniques

Nuclear DNA Measurements Using DAPI (*Method of F. Otto, 1994*)

DAPI (4,6-diamidino-2-phenylindole) binds to the minor groove of the double helix. DNA measurement with this

P.1741

fluorescent dye is considered the most precise presently available, yielding measurements capable of distinguishing X and Y chromosome bearing spermatids and XX from XY chromosome bearing lymphocytes. Coefficients of variation in the range of 1% are routinely possible. The dye is excited in the near-ultraviolet (360 nm). Hence, until recently it required a mercury arc lamp for excitation or a very expensive, unstable and inefficient Krypton laser. Now, however, an inexpensive and stable diode light source is available on commercial cytometers (CompuCyte, Cambridge, MA). for excitation in the violet.

Specimen Preparation

Solutions Needed

1. Detergent solution

100 ml distilled water

2.1 g citric acid · H₂O (0.1 M)

0.5 ml Tween 20 (SERVA, Heidelberg, Germany: Cat. No. 37470)

2. Pepsin solution

10 ml 0.1 N hydrochloric acid

25 mg pepsin (Riedel-de-Haen, Seelze, Germany: Cat. No. 20821; 1200 ug)

3. Staining solution (phosphate)

100 ml dH₂O

7.1 g NaH₂PO₄ · 2H₂O

0.2 mg DAPI (Partec, Münster, Germany: Cat. No. 06-5-4001)

4. Staining solution (citrate)

100 ml dH₂O

5.9 g citric acid trisodium salt · 2H₂O

0.2 mg DAPI

The pepsin solution is not stable; prepare immediately before use. Other solutions are stable at room temperature for 2 weeks. DAPI staining solutions should be stored in the dark.

1. Cells in suspension (blood cells, effusions, tissue culture suspensions) require no pretreatment except for suitable anticoagulation, and are measured fresh or after fixation, usually directly in 70% ethanol or after **brief** (30 sec) fixation in cold 1% formalin followed by ethanol.
2. Cells from bone marrow are put into suspension by vigorous agitation in calcium and magnesium free PBS with EDTA, then treated as above.
3. Cells from solid tumors are brought into suspension by mincing with crossed scalpels in detergent solution for 20 min at room temp. The cell suspension is separated from residual solid tissue by aspiration, then centrifuged and the cell button resuspended and fixed in 70% ethanol.

Fixed cells can be stored at 4°C or -20°C for up to several months.

Staining

1. Cells in fixative are centrifuged at 200g for 10 min to remove the fixative and may be resuspended in saline and centrifuged again if necessary to be certain that the fixative is completely removed.
2. The centrifuged sediment of cells not previously treated by detergent are resuspended in one volume of pepsin solution and incubated for 15 min at room temp with gentle shaking. Then 9 volumes of staining solution are added.
3. Cells from solid tissues that were previously treated with detergent are resuspended in one volume of detergent solution and incubated at room temp for 10 min with gentle shaking. Then 6 volumes of staining solution are added.

The cells in staining solution are stable for 24 to 48 hours at room temp but the best histograms are obtained at about 24 hrs.

Chicken or trout erythrocytes, or murine or human lymphocytes, can be used as internal or external standards, and can be stored in 70% alcohol for at least 6 months.

It should be remembered that DAPI preferentially stains AT-rich DNA, which may affect comparisons of DNA content across species: however, it has no practical effect on relative measurements of benign or malignant human cells.

Nuclear DNA Measurements Using Propidium Iodide (PI) (*Method of L. Vindeløv and I. Christensen*)

Propidium iodide is the most widely used DNA stain for flow cytometry. It is excited by the blue (488 nm) light of an Argon ion laser, standard on all commercial orthogonal flow cytometers, and DNA measurements with coefficients of variation around 2% are obtained routinely. It is the favored DNA stain for clinical applications because the red emission of PI is easily separated from the green emission of fluorescein when the latter is used in dual staining methods to

measure other cell constituents.

Specimen Preparation

Analysis is carried out on fresh, unfixed specimens. Samples can be stored long-term, if desired, frozen in citrate buffer with dimethyl sulfoxide (DMSO).

Solutions Needed

1. Citrate buffer

Sucrose (BDH)	85.50 g (250 mM)
Trisodium citrate · 2 H ₂ O (Merck)	11.76 g (40 mM)
Dissolve in · H ₂ O	approx 800 ml
Add DMSO (Merck)	50 ml
Add · H ₂ O to a volume of	1000 ml
Adjust pH to	7.6

2. Stock solution

Trisodium citrate · 2H ₂ O (Merck)	1000 mg (3.4 mM)
Nonidet-P40 (Shell)	1000 µl (0.1% v/v)
Spermine tetrahydrochloride (Serva, Cat. No. 35300)	522 mg (1.5 mM)
Tria (Sigma, Cat. No. T-1378)	61 mg (0.5 mM)
Add dH ₂ O to a volume of	1000 ml

3. Solution A

Stock solution	1000 ml
Trypsin (Sigma, Cat. No. T-0134)	30 mg
Adjust pH to	7.6

4. Solution B

Stock solution	1000 ml
Trypsin inhibitor (Sigma, Cat. No. T-9253)	500 mg
Ribonuclease A (Sigma, Cat. No. R-4875)	100 mg
Adjust pH to	7.6

5. Solution C

Stock solution	1000 ml
Propidium iodide (Fluka)	416 mg
Spermine tetrahydrochloride (Serva, Cat. No. 35300)	1160 mg
Adjust pH to	7.6

P.1742

Citrate buffer is stored at 4°C. Staining solutions are stored in aliquots of 5 ml in capped plastic tubes at -80° C. Tubes with solution C are wrapped in aluminum foil to protect PI from light. Before use, solutions are thawed in a water bath at 37°C, but not heated to 37°C. Solutions A and B are used at room temperature; solution C is kept in an ice bath.

Method

Cell suspensions are obtained by mechanical disaggregation using a 25 gauge needle on a disposable syringe. The needle is moved back and forth in different directions within the tumor, collecting material in the needle without allowing it to enter the syringe. The needle is flushed with 200 µl citrate buffer and the procedure repeated until 10^6 cells are obtained. The cells are stained and measured that day or frozen in citrate buffer and stored at -80°C.

Staining

Staining is performed by stepwise addition of the staining solutions, as follows:

1. 1800 µl solution A is added to 200 µl cell suspension in citrate buffer and the contents mixed gently by inverting the tube 2 or 3 times while incubating for 10 min at room temp. Too much agitation will increase cell debris and cell clumping.
2. 1500 µl solution B is added and again mixed gently by inverting the tube during another incubation of 10 min at room temp.
3. 1500 µl ice cold solution C is added to stop the staining reaction.
4. The solution is mixed by inversion and the sample is filtered through a 25 µm nylon mesh into tubes wrapped with aluminum foil to protect the PI from light. The sample is kept in an ice bath until measured by flow cytometry, which should be between 15 min and 3 hrs. In the case of sparsely cellular specimens the final cell concentration can be increased by halving the staining solutions.

Chicken and/or trout red blood cells in citrate buffer are used as an internal standard, and, like diagnostic cell samples, they can be kept frozen at -80°C for at least 5 yrs without deterioration. If used together, a ratio of CRBC : TRBC = 4: 7 will produce peaks of equal height in the histogram. The standard cells are added in an amount equal to 20% of the cells in the diagnostic sample.

Simultaneous Analysis of Cellular RNA and DNA by Acridine Orange Staining (Method of Z. Darzynkiewicz, 1944)

Acridine orange (AO) is a metachromatic fluorescent dye that is uniquely capable of differentially staining single stranded (RNA) and double stranded (DNA) nucleic acids. Whole cells or cell nuclei are stained in suspension in a solution of the dye, and the free dye is in a complex equilibrium with dye bound to the nucleic acids of the cells. The basis for differential

staining lies in the very different form of dye binding to double stranded and single stranded nucleic acids, and differences in the affinity of binding. Briefly, the mechanism of staining is as follows: AO binds to double stranded (ds) nucleic acid by intercalation within the helix to fluoresce green when excited by blue light. It binds to single stranded (ss) nucleic acid by insertion between the bases to form solid-state stacks of alternating dye-base composition with red luminescence when excited by blue light. Some RNA in the cell is double-stranded (rRNA; tRNA) and must be selectively denatured under conditions that leave ds DNA intact. This is accomplished under stringent conditions of AO concentration in the presence of EDTA, high ionic strength of the staining solution and pH. The differential staining of DNA and RNA is critically dependent on the concentration of free (unbound) AO, which remains in equilibrium with bound dye in the final staining solution and during measurement. If, for example, cell density exceeds $2 \times 10^6/\text{ml}$ the amount of bound dye is increased, free dye concentration is reduced and denaturation of RNA will be incomplete.

Specimen Preparation

Solutions Needed

1. Stock solution of acridine orange

Dissolve high purity AO (Molecular probes, Eugene, OR.; Cat. No. A 1301) in dH₂O to obtain 1.0 mg/ml concentration. May be kept in the dark at 4°C for several months.

2. Solution A

Triton X-100, 0.1% (v/v) (Sigma, St. Louis, MO) (necessary only if unfixed cells are to be stained).

P.1743

HCl, 0.08 M (final concentration)

NaCl, 0.15 M (final concentration)

Prepare by adding 0.1 ml Triton X-100, 8 ml 1.0 M HCl, 0.877 g NaCl and sufficient dH₂O to a volume of 100 ml. May be stored at 4°C for several months.

3. Solution B

Acridine Orange 6 µg/ml (~20 µM)

EDTA-Na, 1 mM

NaCl, 0.15 M

Phosphate-citric acid buffer, pH 6.0

Prepare 100 ml buffer by mixing 37 ml 0.1 M citric acid with 63 ml of 0.2 M Na₂HPO₄.

Add 0.877 g NaCl, stir until dissolved.

Add 34 mg EDTA disodium salt. Stir until dissolved.

Add 0.6 ml stock solution of AO (1 mg/ml).

May be stored for several months at 4°C in the dark.

4. Nuclear isolation solution

- 10 mM Tris buffer (pH 7.6)
- 1 mM Na citrate
- 2 mM MgCl₂
- 0.1% (v/v) non-ionic detergent Nonidet (NP-40).

Staining

1. Fix cells in suspension in 70% ethanol on ice.
2. Centrifuge, remove all ethanol, rinse once and resuspend in Hank's buffered saline (HBSS) at a cell density less than 2×10^6 /ml.
3. Transfer a 0.2 ml aliquot of cell suspension to a small tube, keep on ice.
4. Add gently 0.4 ml of ice cold solution A, on ice. Wait 15 sec.
5. Add gently 1.2 ml of ice cold solution B. Measure cell luminescence during the next 2 to 10 min, to allow for equilibrium.

The specificity of staining can be assessed by incubations with exogenous RNase or DNase.

Unfixed cells in suspension at a density of less than 2×10^6 /ml may be stained as above (steps 3-5).

Nuclear RNA can be measured (with DNA) in cells stripped of cytoplasm. The nuclear isolation technique is as follows:

Place trimmed fresh tissue in nuclear isolation solution and mince finely with crossed scalped blades or scissors. Pipette several times with a Pasteur pipette or large gauge needle until clean nuclei are released into the supernatant (check by phase microscopy). Filter the nuclear suspension through a 40-60 μ nylon mesh and resuspend in nuclear isolation solution at a concentration of 2×10^6 nuclei/ml.

Fix cells in 70% ethanol on ice then stain and measure as above.

DNA Assays of Paraffin-Embedded Specimens (*Method of D. W. Hedley, 1994*)

Tissues fixed in formalin and embedded in paraffin are remarkably durable, even for decades, and DNA in the cells of most such tissues is sufficiently preserved for flow cytometry assays. DNA measurements are generally of poorer quality than in the case of fresh or freshly fixed specimens, and there is more debris. Nevertheless, useful determinations of tumor DNA index and S-phase fraction are possible.

Specimen

1. The tumor, tissue or cellular specimen to be examined must be adequately represented in the selected paraffin block. The specimen in the block may be trimmed to eliminate as much non-neoplastic tissue as possible,^{*} and a conventional histologic section is cut and examined to confirm the nature of the sample.
2. One to four thick ($\geq 50 \mu$) sections are cut on a microtome and can conveniently be carried through the following processes in a nylon mesh bag. Sections that are any thinner will contain too many transected nuclei and too much cellular debris.

3. Dewax in 2 or 3 changes of xylene, as necessary, then rehydrate for 10 min each in 100% ethanol followed by 95%, 70%, 50% ethanol and distilled H₂O.
4. Aspirate the H₂O (centrifuge the tissue to a sediment, if necessary to avoid loss), mince and digest in 0.5% high purity pepsin (Sigma # P7012) in 0.9% saline adjusted to pH 1.5 by addition of 2 N HCl. Enzyme digestion is critical. The pepsin solution (1.0 ml) is added to the tissue and digestion carried out with gentle agitation in a water bath at 37°C for 30 minutes or until microscopic examination shows bare nuclei or whole cells similar to those in the histologic section.
5. Following digestion, nuclei should be washed and resuspended in buffered medium, filtered through a nylon mesh and adjusted to approximately 10⁶ cells/ml.
6. Staining is preferably with DAPI or propidium iodide, and requires RNase to remove any nuclear or residual cytoplasmic RNA.

Immunocytochemical Assays for Leukemias/Lymphomas (*Technique at Westchester Medical Center, courtesy of M. Kajstura*)

Clonal proliferation of the hematopoietic cells of leukemia or lymphoma can be identified by immunocytochemistry and quantified by cytometry.

Diagnosis and classification of leukemia/lymphoma is based on the detection of a clonal population of cells expressing antigens of an immature or inappropriate cell type.

Sample Requirements

Bone marrow or peripheral blood: Collect 1 ml of blood or marrow in a 3 ml (or larger) sodium heparin (green top)

P.1744

tube. Specimen may be stored at room temperature for 24 hrs; to store longer (48-72 hrs), add 1 ml of RPMI.

Lymph nodes: Dissociate cells mechanically in RPMI culture medium with crossed scalpel blades or by gently probing with a 25 gauge needle. Sieve cell suspension through a 25 µm nylon mesh. Store single cell suspension in 10% fetal bovine serum (FBS) in RPMI at 4°C. Check viability of lymph node suspension with trypan blue (not necessary for blood or marrow unless visibly hemolysed or older than 24 hrs.)

Cell Sample Preparation

1. Check WBC count (dilute bone marrow 1 : 4 with RPMI prior to counting).
2. Adjust concentration of the specimen up to 10 × 10⁶/ml with RPMI (cell-to-reagent ratio different than recommended may result in an altered pattern of staining).
3. Allow any visible particles to settle (or remove by sieving through a nylon mesh), and transfer the cell suspension to another (labeled) tube.
4. Label each tube with the last name of the patient and with the marker or combination of markers or an isotype control for each of the selected markers.

1 ml of a cell suspension at 10 × 10⁶/ml is required for up to 20 tubes with 3-color combination of markers for immunophenotyping.

Selection of markers varies depending on the expected abnormality as determined by review of the bone marrow or peripheral blood differential count, or examination of the histologic section of the lymph node, in conjunction with any special hematologic stains.

Isotype controls corresponding to the antibody subclass of CD markers used to stain cells should be incorporated into an antibody panel.

Staining Procedure

1. Add 50 μ l of cell suspension to each labeled tube.

If any surface immunoglobulin (slg) markers are to be measured (e.g., IgG, kappa, lambda), the cell suspension must be washed twice with 4 ml of RPMI to remove plasma immunoglobulins and the specimen treated with blocking solution to block FC receptors.
2. Add 10 μ l (or manufacturer's recommended amount) of each monoclonal antibody reagent to corresponding labeled tubes; change pipette tip and wipe pipette between each reagent. Vortex briefly (3 seconds; overvortexing will adversely affect scatter properties).
3. Incubate tubes in the dark at room temperature for 20-30 min.
4. Add 2 ml FACS lysing solution (Becton-Dickinson). Vortex immediately and incubate in the dark for 7 min (may be done in covered centrifuge).
5. Centrifuge at 300 g for 5 min. Decant supernatant (repeat lysing step with 0.5 ml of lysing solution for 2 min. if sediment is not white).
6. Resuspend and wash twice in PBS wash solution (1% PBS with 1% FCS and 0.1% NaN₃). Centrifuge between washes at 300 g for 5 min.
7. Decant supernatant and resuspend stained cells in 0.5 ml of 0.5% formalin.
8. Mix and run in flow cytometer (or cover with parafilm and store at 4°C for up to 48 hrs before running).

Acquisition and analysis of data performed using CELL-Quest software (BD).

Intracellular Antigens Staining Procedure

1. Place 5×10^5 cells in each tube and add 10 μ l of conjugated surface markers.
2. Vortex each tube gently and incubate for 15 min at room temperature in the dark.
3. Add 3 ml PBS wash solution to each tube and centrifuge 5 min. at 450 g.
4. Add 100 μ l of fixation reagent (medium A) (FIX & PERM Cell Permeabilization Kit—CALTAG).
5. Incubate for 15 min at room temp.
6. Add 3 ml PBS wash solution to each tube and centrifuge 5 min at 450 g.
7. Add 100 μ l of permeabilization reagent (medium B) and 10 μ l of CD marker targeting intracellular component and isotype control to respective tubes.
8. Vortex each tube gently and incubate for 15 min at room temperature in the dark.
9. Wash with 3 ml PBS wash solution and centrifuge 5 min at 450 g.
10. Decant the supernatant and add 0.5 ml of PBS wash solution (do not use fixative).
